Ironically, in hand joints high levels of grip strength may act like a vise to excessively increase joint loading and thereby increase the risk of OA in proximal hand joints. Thus metacarpophalangeal joints of the hands and the joints at the base of the thumb are at high risk of OA when grip strength is increased.⁴⁵ It is not clear whether this same relationship exists for other joints.

Hip osteoarthritis and abnormalities of joint shape

When the proximal and distal sides of a joint fit together normally, load is distributed physiologically. When one of the bones is misshapen, either due to a developmental abnormality or as a result of injury, this can introduce increased levels of focal load (stress) across the joint. The increase may be modest and the effects may not be immediate; it may take many years for the increased loading to generate the joint injury that represents OA. Abnormal bone shape likely accounts for a large percentage of hip OA in the community. A variety of shape abnormalities can occur. One is hip dysplasia in which there is an underdevelopment of the acetabulum leading to undercoverage of the femur and excess focal stress where the edge of the acetabulum contacts the femur. Others include a nonspherical femoral head or an acetabulum that extends too far around the femoral head; both of these latter problems can cause femoroacetabular impingement (FAI).⁴⁶ Longitudinal studies suggest that FAI is an important cause of later hip OA.⁴⁷⁻⁵⁰ The consequences of any of these abnormalities is that the person with the abnormality is at high risk of developing hip OA; the age at which the disease develops is related to the severity of these abnormalities and may be a consequence of use-related factors (particular sports other activities).

Although FAI is slightly more common in men than in women, the presence of hip dysplasia in early childhood is far more common in girls than in boys and can sometimes be identified and corrected at birth. Milder forms of dysplasia of the acetabulum are likely not identified at birth and survive into adolescence and adulthood, causing later hip OA.

Chinese persons, both in China and in the United States,⁵¹ have a much lower risk of hip OA than whites in the United States.⁵² Morphometric analyses of nondiseased hips in Chinese and white women⁵³ showed that FAI changes were far more common in whites, which suggests that this anatomic abnormality is the likely source of racial differences in hip OA prevalence.

Risk factors relating to loading of the joint

OA develops as a consequence of impaired joint physiology on which is superimposed excess loading. In the context of a physiologically normal joint without a previous injury, normal levels of human physical activity are unlikely to cause disease. For example, marathon runners who do not run professionally do not appear to be at any increased risk of knee OA.⁵⁴ OA occurs when that loading occurs in an environment in which the joint is already injured or impaired or in which the loading is so excessive or injurious that even a normal, well-functioning joint cannot tolerate it without injury. For example, marathon runners who have sustained previous meniscal tears are at extremely high risk of later OA of the knee. Also, Olympic team marathoners and professional runners, who probably subject their knees and hips to a quantity of loading that may be beyond normal physiologic adaptation, are at high risk of later hip and knee OA.⁵⁴⁻⁵⁶

Loading is not a simple construct. There is the quantity of a given load during a step or use of a joint, a quantity that might be affected by the strength of muscle contraction; the load borne by a weight-bearing joint would be increased in an obese person, for example. Then the joint might be at risk based on the speed with which that load was applied (e.g., a runner would apply more load to the knee than a walker). Understanding the effect of loading on the development of OA will necessitate disentangling different types of load and their relative effects on joint function, especially in an environment in which joint-protective mechanisms might be impaired.

Obesity

Being overweight increases a person's risk of developing knee OA. For women the risk of disease increases monotonically with weight. This may or may not be true for men because studies conflict on this matter, but among men it is clear that being obese or very overweight increases the risk of knee OA.^{13,57} In general, the relation of obesity with knee OA is stronger in women than in men.

For hip OA the relation of obesity is less strong and less clear. The development of new-onset symptomatic OA is increased in persons who are obese, as is the risk of developing bilateral radiographic disease, although there is no significant or consistent relationship between obesity and the development of unilateral OA of the hip.^{57,58} The weaker relationship of obesity with hip OA than with knee OA may be because hip OA is often caused by hip shape abnormalities (see earlier), and weight therefore may play a lesser role in hip disease.

Obese persons have more severe pain than nonobese persons with the same level of radiographic disease, and they also tend to be more functionally limited. Weight loss studies suggest a modest effect on improvement of symptoms for those with knee OA, although the amount of weight loss achieved in these trials has been relatively small (5 to 10 kg). Studies of persons undergoing bariatric surgery, which produces massive weight loss, have shown a dramatic improvement in knee OA symptoms, which suggests that if weight loss were sufficient, patients' symptoms would improve.⁵⁹ Indeed, recent randomized trials in which those assigned to calorie restriction achieved sustained weight loss suggest that a major improvement in knee pain can be achieved, especially if the weight loss is accompanied by an increase in physical activities such as walking.⁶⁰

Obesity could cause disease through two different mechanisms. First and most obviously, it could produce excessive load that then leads to joint deterioration. In fact, each pound of increased weight increases loading across the knee by 3 to 6 pounds.⁵⁷ However, studies also suggest that obese persons are at a higher risk of hand OA than persons who are not obese.⁶¹ In all likelihood, there is no increase in load across hand joints in persons who are obese. Therefore another explanation for obesity's effect on OA is that obesity may have metabolic effects on joints, which in turn produce some joint degeneration including cartilage loss. Obesity has a far greater effect on knee OA than it has been shown to have on hand OA, which suggests that most of the effect of obesity can be explained by its effect in producing excess load. Studies so far have failed to identify a metabolic factor that affects OA occurrence.⁵⁷

Physical activity: injurious or protective?

Physical activity is greatly varied and so are its effects on the joint. Furthermore, at different stages of disease the effects of physical activity may differ, so that in a normal joint, activity and loading across the knee might have trophic effects on joint cartilage and other structures, whereas in joints that are damaged, particular types of physical activity might be injurious. Given the various types of physical activity and their likely different effects at different stages of joint diseases, it is not surprising that the results of studies evaluating effects of physical activity on OA vary tremendously. Some studies suggest that physical activity might actually protect against the occurrence of disease, whereas others point to a heightened risk of disease or its progression in those who engage in particular types of physical activity or who already have diseased joints. These conflicting data suggest that there is no single answer to the whether physical activity causes or protects against OA. The relation of physical activity to disease may depend on the specific activity and stage of disease.

Epidemiologic studies that have incorporated such MRI findings of OA as cartilage defects and bone marrow lesions have been a bit more consistent in suggesting that physical activity increases the risk of joint damage. For example, in a cross-sectional study, those with no knee pain but with high physical activity scores had more evidence of cartilage loss, meniscal damage, and other findings of OA than those with lower activity scores.⁶² Further, in persons who had MRI evidence of knee joint damage at baseline, damage to the joint worsened over time more often if the individuals walked more than 10,000 steps a day than if they walked less than this amount.⁶³ Even so, studies including MRI assessments have not been consistent in their findings.⁶⁴

In nondiseased joints in middle-aged women, physical activity has been associated with increased joint space, and in one study of persons who had experienced injury but did not have OA, physical activity actually led to an improved biochemical profile within cartilage as documented by biochemical imaging of cartilage.⁶⁵ Further, in recreational runners, running marathons (at least occasionally) does not increase the risk of getting knee OA. Moreover, in older persons, self-reported heavy levels of activity and walking

several miles a week did not increase joint space loss or MRI findings of cartilage loss. This was true even in a group of persons with knee OA, which suggests that walking may be an exercise that, even in vulnerable knees, is not risky.⁶⁶

If physical activity does not consistently increase the risk of OA in the knee and other joints, when and in whom might it pose a risk? First, as noted earlier, elite marathon runners—those on Olympic teams and who run professionally—are at a high risk of developing knee and hip OA at a relatively early adult age (in their 30s or 40s).⁵⁶ Second, those whose jobs require manual labor with repetitive activities that load a specific joint excessively and repeatedly tend to get OA in the overused joint (e.g., cotton pickers in hand joints; miners in backs and knees), which suggests that even normal joints can develop OA if these joints are forced to do the same laboring task for hours every day and many weeks each year over many years. Lastly, marathon runners who have already had meniscal tears are at high risk of advanced OA if they continue to run.⁶⁷ Studies of physical activity and OA have been greatly limited by the challenge in accurately assessing physical activity patterns in people. Surveys of self-reported physical activity are highly imprecise and may not identify those who are especially active in ways that might be dangerous to their knees or hips. In the meantime,

those with disease are at heightened risk of disease progression if they continue to engage in impact-loading activities that might have led to the joint injury in the first place; thus football players with knee injuries will get worse disease if they continue to play.

The peculiar case of bone mineral density: is it systemic or local?

High bone mineral density increases the risk of knee and hip OA independently of other factors such as obesity and strength. The relation of high bone mineral density to hand OA is less consistently reported, and bone mineral density probably has no effect on the risk of progressive OA.⁶⁸

One explanation for the relation of high bone mineral density with knee and hip OA could be that high bone mineral density in the lumbar spine and proximal femur reflects long-standing high levels of physical activity and obesity, both of which load these bones. The same factors may be tied to increased risk of knee and hip OA. However, that would not explain any relation of high bone mineral density with hand OA, which has been shown in some studies.⁶⁹ This well-known association of high bone mineral density with OA risk remains a mystery.

Clinical features of osteoarthritis

■ ROY D. ALTMAN

- Osteoarthritis (OA) is the most common articular disease.
- About 50% of persons with radiographically evident OA have symptoms.
- Pain is the most common reason why a patient with OA consults a physician.
- Pain in OA has many potential sources. There is no direct pain from cartilage, synovial fluid, or the inner two thirds of menisci. Pain fibers are present in the remaining tissues surrounding the joint.
- A variety of other symptoms can result from OA that affect function and quality of life.
- Signs of OA can be absent, subtle, or severe.
- Although OA can involve virtually any joint in the body, the most commonly affected joints are hands and feet, hips, and knees.

INTRODUCTION

Osteoarthritis (OA) is the most common form of arthritis, accounting for 30% of physician visits.¹ It may be defined as a “heterogeneous group of conditions that lead to joint symptoms and signs which are associated with defective integrity of articular cartilage, in addition to related changes in the underlying bone and at the joint margins.”² More specifically, OA is “usually a progressive disease of synovial joints that represents failed repair of joint damage that results from stresses that may be initiated by an abnormality in any of the synovial joint tissues, including articular cartilage, subchondral bone, ligaments, menisci (when present), periarticular muscles, peripheral nerves, or synovium. This ultimately results in the breakdown of cartilage and bone, leading to symptoms of pain, stiffness and functional disability. Abnormal intra-articular stress and failure of repair may arise as a result of biomechanical, biochemical and/or genetic factors. This process may be localized to a single joint, a few joints, or generalized, and the factors that initiate OA likely vary depending on the joint site.”³ OA is usually classified as either primary (idiopathic) or secondary (i.e., associated with a known condition). Although OA is present by histologic or radiographic criteria in nearly 80% of people by the age of 80 years, at any age only half have symptoms.⁴ Symptoms are often variable and intermittent. OA affects as many as 12% of the U.S. population between the ages of 25 and 74 years.⁵ There is a modest correlation between the presence of symptoms and the severity of anatomic or radiographic changes.

Although variable in its presentation and course, OA often carries significant morbidity. In addition to the effects on the individual, the cost of OA to society is also significant,¹ related to its high prevalence, the reduced ability of those affected to perform both occupational and nonoccupational activities, the occasional loss of a patient's ability to undertake self-care, and the related drain on health care resources.⁶

OA is no longer considered a “degenerative” or “wear and tear” arthritis but rather involves dynamic biomechanical, biochemical, and cellular processes.⁷ OA is currently viewed as a disease of the entire joint and, therefore, the failure of the joint as an organ.⁸

Although the lesions of OA are almost always bilateral, there is a tendency for one side to be more symptomatic than the other. The symptomatic side may alternate over time. The presence of unilateral disease may suggest OA secondary to trauma. In contrast to systemic inflammatory arthritides, OA lacks constitutional symptoms (e.g., fever, weight loss, malaise).

When OA is symptomatic, the most prominent complaint is pain. It remains unclear why fewer than 50% of persons with severe radiographic

OA (Kellgren and Lawrence⁹ grade III and IV) report pain.¹⁰ Most often, symptoms of OA are insidious in onset, but flares can occur. Symptoms and signs of OA are listed in [Box 173.1](#).

SYMPTOMS

Pain

Pain is the most common reason why a patient with OA seeks the help of a physician.¹¹ The pain of OA changes during the day and has been demonstrated to vary by 20% within a given week and from week to week.¹² Pain in OA is also influenced by pain at other sites and by patient adaptation and avoidance strategies, and it is inextricable from function.¹³ The pain of OA is associated with poor sleep, fatigue, changes in mood, and impaired quality of life. When pain is present, determining the cause is difficult ([Table 173.1](#)).¹⁴ In knee OA, patients may localize their pain to a compartment of the knee or to the front of the knee but will most often describe their pain as poorly localized. Joint pain is often referred distally; for example, hip pain may be referred into the thigh or knee. Anterior knee pain may represent patellofemoral (anterior compartment) OA. Patients often ascribe increasing pain and stiffness to changes in weather, particularly changes in barometric pressure and ambient temperature.¹⁵ Patients with unilateral knee pain commonly develop bilateral disease (80% by 12 years).¹⁶

The severity of pain should be noted and ideally measured at each visit. The three most commonly used pain scales are the five-point Likert scale (0 = none, 1 = mild, 2 = moderate, 3 = severe, 4 = very severe), the 100-mm visual analogue scale (from 0 mm = no pain to 100 mm = the most pain possible), and the 11-point numerical rating scale (from 0 = no pain to 10 = the most pain possible).

Pain can also be measured through standardized testing. For the hip or knee, the Western Ontario McMaster Universities (WOMAC) Osteoarthritis Index quantifies pain, stiffness, and function in separate subscales. The algofunctional index of Lequesne measures hip or knee pain and function in a single scale. The WOMAC index has been incorporated into the Hip Dysfunction and Osteoarthritis Outcome Score (HOOS) and the Knee Dysfunction and Osteoarthritis Outcome Score (KOOS). Because of the often cyclic nature of OA, an 11-item tool, the Measure of Intermittent and Constant Osteoarthritis Pain (ICOAP), has been developed.¹⁷ For the hand, validated scales include the Australian-Canadian Hand Osteoarthritis Index (AUSCAN) and the Functional Index for Hand Osteoarthritis (FIHOA).¹⁸

The quality of the pain may hint at its pathologic origin. Pain that occurs after exercise is often caused by subchondral ischemia—so-called bone angina. This pain is often aching and deep seated. Pain along the joint margin, with tenderness at the site, may indicate periosteal pain from stretching of the capsule or ligaments or overgrowing osteophytes. The sudden onset of pain with a catching sensation of the knee may be associated with a torn meniscus or a loose body inside the joint. Knee pain accentuated by sitting on a low chair or couch is often patellofemoral in origin. Among individuals 50 years of age or older, 57% with knee pain had pain in at least two other joint areas.¹⁹

There has been considerable progress in the understanding of pain mechanisms (see Chapter 24).²⁰ Identifying the source of pain may help direct therapy. Contributions of the different articular tissues to pain are discussed next.

Damage to articular cartilage

Damage to articular cartilage is a hallmark of OA; yet articular cartilage normally lacks nerve endings and is not a direct source of pain.^{21,22} Menisci similarly do not contain nerves in their weight-bearing surfaces (i.e., the

BOX 173.1 SYMPTOMS AND SIGNS OF OSTEOARTHRITIS

Symptoms	Signs
■ Pain	■ Altered gait
■ Discomfort	■ Tenderness
■ Depression	■ Hard tissue enlargement
■ Stiffness	■ Swelling with/without effusion
■ Reduced function	■ Crepitus
■ Weakness	■ Limitation of motion
■ Grinding or clicking	■ Deformity

TABLE 173.1
Relationship between anatomic site and possible physiologic mechanism for pain in osteoarthritis

Anatomic site	Mechanism
Cartilage (defective or lost)	<i>Synovial:</i> inflammation induced by cartilage “char” fragments, cartilage crystal shedding, cartilage release of cytokines (e.g., interleukin-1), enzymes (e.g., metalloproteinases) <i>Subchondral bone:</i> mechanical stress (see below) <i>Instability:</i> stress on capsule
Menisci	Tear or degeneration: stretch at insertion to the joint capsule, catch between surfaces
Synovial cavity	Stretch of joint capsule, transport of inflammatory mediators between synovium and cartilage
Synovium	Inflammation, hypertrophy
Subchondral bone	Ischemia with increased subchondral pressure, decreased oxygen tension, and increased pH Avascular necrosis Regeneration or repair of infarcted bone
Osteophytes	Periosteal elevation Neural impingement
Joint capsule	Stretch from joint distention Stress at insertion to periosteum and bone
Ligaments	Stress at insertion to periosteum and bone
Bursae	Inflammation, with or without calcification
Muscle	Spasm, contracture Nocturnal myoclonus
Central nervous system	Depression, anxiety, fibromyalgia, nonrestorative sleep
General	Ethnic and cultural factors, coping skills, prior pain experience, abuse Altered function placing stress on other areas of the musculoskeletal system

inner two thirds) and cannot directly account for pain. Nevertheless, abnormalities in articular cartilage, menisci, and even synovial fluid can indirectly cause pain in OA.

Damaged articular cartilage indirectly causes pain due to loss of its structural integrity, alteration in biomechanics, cartilage debris, and release of inflammatory mediators. Structural damage to cartilage causes uneven surfaces, which results in a grinding sensation felt by the patient and crepitus on examination, often accompanied by pain.

When damaged cartilage “char” fragments are released into the synovial cavity, the synovium attempts to clear them, precipitating an inflammatory synovial response. Other microscopic and submicroscopic particulate material released from damaged articular cartilage, such as collagen, proteoglycans, and crystals as well as proteolytic enzymes and cytokines, triggers a synovial inflammatory response. Although synovial inflammation is most often less severe than in the traditional “inflammatory” arthritides (e.g., rheumatoid arthritis), activation of inflammatory responses always occurs in OA joints, at both the synoviocyte and chondrocyte level (which justifies the term *osteoarthritis*).²³

Abnormal cartilage may contain a variety of calcium crystals, including calcium pyrophosphate dihydrate, hydroxyapatite, and basic calcium phosphate. Surface disruption may allow crystal shedding into the joint cavity, which stimulates varying degrees of inflammation.²⁴ In cases in which cartilage is fissured and the subchondral bone is exposed, hydroxyapatite crystals from bone or cartilage may leach or be sheared into the synovial cavity. In addition, the absence of articular cartilage allows loosening and instability of the joint and exposure to subchondral bone.

Other loose bodies in the joint, such as “joint mice” or osteochondromatosis, are potential indirect causes of pain. The disrupted portion of torn menisci can be displaced, stretching the joint capsule. Meniscal horizontal fissures do not usually cause symptoms, but fragments of the degenerated menisci may elicit an inflammatory response or act as loose bodies in the joint cavity.

Role of synovial fluid

Synovial fluid can indirectly cause pain by serving as a transport medium, distending the joint capsule, and/or limiting joint function. In OA the synovial fluid may act as a reservoir for inflammatory cytokines, cells, and crystals. In addition, excess synovial fluid distends the joint, which potentially compresses synovial blood vessels and stimulates pressure receptors in the capsule.²⁵ A distended joint compromises the normal transport of nutrition and gases by synovial fluid between cartilage and synovium. The residual waste products linger in the synovial space and perpetuate inflammation.

The synovium contains nerve fibers. These include A β (large myelinated mechanoreceptor), A δ (large myelinated mechanoreceptor/nociceptor), and C (small nonmyelinated nociceptor) fibers.²⁰ The latter can release both substance P and calcitonin gene-related peptide (CGRP). Substance P stimulates both the pain response and inflammation.²⁶

Role of subchondral bone

Subchondral bone is directly related to pain in OA.²⁷ When subchondral ischemia or increased venous pressure occurs, peptides such as substance P and CGRP are released from the nerve endings in bone.²⁸ The pain of ischemic bone is aching and deep seated. In OA, subchondral cysts and sclerosis are radiographic evidence that localized osteonecrosis has taken place. Bone marrow lesions adjacent to the knee, which may represent areas of trabecular remodeling and can be detected by magnetic resonance imaging, are associated with knee pain and compartment-specific structural deterioration.^{29,30}

Osteophytes are the most consistent pathologic and radiographic finding associated with the presence of pain.³¹ Osteophytes may cause pain directly by distending the periosteum; pain can sometimes be elicited by applying pressure over an osteophyte about the knee or interphalangeal joint of the hand.

Damage to meniscus, capsule, and related tissues

Damaged menisci of the knee change the biomechanics of gait, alter the normal joint congruity, catch between joint surfaces, and stretch the joint capsule. Indeed, an abnormal meniscus is an important predictor of OA disease progression.³²

The joint capsule and periarticular ligaments are stretched by synovial effusions, abnormal menisci, or instability and may cause pain through mechanoreceptors and nociceptors. Stress at the ligamentous insertion on the periosteum stimulates nociceptors. When the periarticular tissues are distorted, the ligaments may be abnormally stressed, which induces contractures that result in decreasing function and increasing pain from stress at ligamentous insertions and periarticular muscle spasm.

Periarticular bursae may become inflamed and hence be a source of pain (e.g., anserine bursitis medial and inferior to the knee). Bursal inflammation is sometimes associated with calcium formation (e.g., calcific bursitis).

Muscle spasm is probably a common source of pain in OA. Muscle spasm may occur in the form of nocturnal myoclonus, altering sleep patterns and resulting in fibromyalgia-like symptoms.³³ Muscle spasm of the lower extremities must be differentiated from pain related to vascular causes (e.g., night cramps) or restless leg syndrome and pain of spinal radicular origin. Joint contractures in OA can cause pain on stretching of the periarticular ligaments and muscles.

Psychological factors and pain

The severity of joint pain is modulated by the individual's perception of pain and unique ethnic, cultural, and personal circumstances. It tends to be more severe in the evenings, on weekends, and early in the work week.³⁴ Pain is complicated by the presence of coexistent or induced psychological distress, such as depression. Pain is also influenced by anxiety and secondary gains.

There is altered central pain processing in OA, characterized by a generalized greater sensitivity to pain in response to experimental stimuli.³⁵

Stiffness

Stiffness may be defined as a sensation of a gelling or tightening of the involved joint that usually occurs after inactivity, such as in the morning or when rising after sitting for a prolonged period. The stiffness in OA usually lasts only a few minutes and almost always less than 30 minutes, in contrast to the diffuse stiffness of rheumatoid arthritis. Also, the stiffness in OA is usually confined to the symptomatic joints.

Other symptoms

The patient may have a sensation of fullness and swelling about the joint. There may be associated warmth. Inflammation and/or contraction of weight-bearing joints is associated with gait disturbance, increased muscle spasm, and reduced quality of life. A contracted knee or hip can produce a prominent limp (see later). Aids to ambulation may reduce the severity of alterations in function.

Impaired function of a weight-bearing joint places stress on the contralateral weight-bearing joints. It is not uncommon for the patient with impaired right knee function (perhaps with pain) to have difficulty with the left hip and vice versa.

Hypertrophic bone formation in interphalangeal joint OA may contribute to reduced dexterity and difficulty performing fine motor movements, such as knitting, sewing, or playing a musical instrument. OA of the first carpometacarpal (CMC) joint may make it difficult to perform many activities of daily living, such as holding a pen.

Inactivity secondary to pain may lead to significant weakness and can be compounded by periarticular muscle atrophy.

Patients may complain of enlargement of the joints of the hand or knee. They may also complain of increasing deformity of the knees, such as knocked (valgus) or bowed (varus) knees. There may be a click or grinding sensation with joint motion, and this grinding may be associated with pain. In the knee, instability is often associated with a feeling that the knee is “giving out.”

SIGNS

Gait

OA of weight-bearing joints leads to altered gait patterns, mostly caused by a conscious or subconscious attempt to protect the joint. Hip, knee, ankle, and foot arthritis give rise to distinctive gait patterns. Obesity compounds the effects of OA in weight-bearing joints by increasing pressures across joint surfaces and altering gait patterns. Increasing body mass index alters knee adduction, knee flexion, and knee rotation moments during gait, with additional changes in knee flexion moment and flexion angle.¹⁶ Alterations in gait aggravate pain in other weight-bearing joints and the low back.

OA of the hip or knee frequently is associated with significant changes in the periarticular muscles, often with atrophy and weakness. Reduced muscle strength is compounded by reduced proprioception.³⁶

Tenderness

There may be tenderness of soft tissues (e.g., synovium, capsule, bursae, and periarticular muscles) or periosteum at the insertion of capsule or ligaments.

Joint swelling

There may be enlargement of the joint from synovitis, synovial effusion, or bony enlargement. Effusions are usually cool or slightly warm to palpation. Effusion of the distal interphalangeal (DIP) joint may present as a cystic herniation (Fig. 173.1); aspiration often reveals a jellylike material reminiscent of a ganglion cyst. Swelling of the joint from an effusion frequently leads to loss of extension.

Crepitus

Grinding, crunching, or cracking may be heard over a joint with OA. Crepitus is caused by movement of uneven surfaces across each other and is best demonstrated with active motion of the joint. This contrasts with the benign “cracking” of the proximal interphalangeal (PIP) joints that occurs when

Fig. 173.1 Interphalangeal osteoarthritis of the hand, with cystic herniation of the fifth proximal interphalangeal joint.

smooth cartilage surfaces are separated, which creates a vacuum sound with release of nitrogen gas.

Limitation of motion

There may be loss of function with reduced motion as a result of pain, synovitis/effusion, or periarticular soft tissue contractures. When motion of a weight-bearing joint is limited, additional stress is placed on ipsilateral and contralateral weight-bearing joints.

Deformity

Deformity may be present in any of the peripheral joints with OA. However, it is most notable in the interphalangeal joints of the hands with enlargement and subluxation, in the first CMC joint, in the knees (varus/valgus deformity), or in the hips (shortened extremity). Deformity may be associated with joint fusion or instability.

Instability

Range-of-motion examination may reveal instability in various planes of motion. For example, instability of the knee may be demonstrated in the anteroposterior planes (cruciate ligament laxity or deficiency) or in the mediolateral planes (loss of meniscus, collateral ligament laxity, loss of medial compartment bony stock).

CLINICAL PRESENTATIONS

OA may involve virtually any joint in the body. Because there is usually an insidious onset of symptoms, an acute presentation suggests a concomitant inflammatory component (e.g., microcrystalline synovitis). OA is most often monarticular in presentation, slowly evolving to the contralateral side.

There are patterns to joint involvement. In general, OA of the knees and hips occurs in a monarticular or oligoarticular distribution. OA of the hands and OA of the feet are generally present in the same individual to varying degrees. There is a subgroup of patients who have OA in three or more joint groups, which is known as *generalized OA*.³⁷ The characteristics of OA at some individual sites are discussed next.

Shoulder

Shoulder pain is sometimes related to glenohumeral OA. Pain is typically aching and is associated with extremes of motion or occurs after activity of the shoulder. OA of the shoulder usually coexists with, and is difficult to

Fig. 173.2 Destructive arthropathy (Milwaukee) of the shoulder. A large synovial effusion is apparent over the lateral aspect of the humerus (a) or anteriorly in front of the glenohumeral joint (b).

Fig. 173.3 Interphalangeal osteoarthritis of the hands. Knobby, hard tissue changes of the distal interproximal joints as well as hard and soft tissue changes of the proximal interphalangeal joints with deformity are seen. The metacarpophalangeal joints and wrists are spared. There is knobby deformity at the base of the left thumb, reflecting radial subluxation of the first proximal metacarpal at the first carpometacarpal joint.

differentiate from, other abnormalities of the shoulder (e.g., rotator cuff abnormalities, adhesive capsulitis, labrum, and bursitis). Symptomatic shoulder OA appears to be more common than previously recognized.

A peculiar destructive arthropathy (Milwaukee shoulder) is associated with persistent shoulder pain, large synovial effusions, and demonstration of a variety of synovial fluid calcium crystals (Fig. 173.2) (see Chapter 191).

Acromioclavicular joint OA can produce pain that can be aggravated by weight bearing or other stressful activities. Painless enlargement of the acromioclavicular and sternoclavicular joints is commonly associated with reduced shoulder motion.

Hands

Patients often have unsightly enlargement of digits that may or may not be painful, or pain at the base of the thumb. Examination demonstrates hard tissue (bony) enlargement and deformities of the interphalangeal joints. There may be tenderness and occasionally other signs of inflammation. There is often a partial loss of range of motion and subluxation. The European League Against Rheumatism has developed diagnostic criteria for hand OA.³⁸

DIP joints are typically involved, with slow bony enlargement over a period of years (Heberden nodes) (Fig. 173.3). Heberden nodes are more commonly symptomatic in women than in men and often are present in more

than one family member. In women they frequently appear around the time of the menopause, but a clear relation to reduced estrogen concentrations has not been established. The enlargement is not confined to any one aspect of the joint, although there is a predilection for the radiodorsal and ulnodorsal aspects of the joints. Involvement of the second and third DIPs is particularly common. Enlargements are often more severe in the dominant hand. There is frequently associated deformity, with radial, ulnar, or palmar deviations; these are most often unsightly rather than painful. A predominantly palmar subluxation may give the appearance of a mallet finger. There is often some loss of dexterity. There may be an acute swelling of the DIP joint, with cystic herniation of the capsule (see Fig. 173.1). Aspiration of these cysts yields a jellylike material. Microscopic examination reveals large polymorphonuclear leukocytes, with many refractile inclusion cysts that stain for fat (reminiscent of the fluid extracted from a wrist ganglion).

There are often associated hard and/or soft tissue changes in the PIP joints (Bouchard nodes) and central bony erosive changes radiographically. Deformities of the PIP joints are particularly common (see Fig. 173.3). The second and third PIP joints are most commonly involved. Involvement of the MCP joints occurs but is decidedly less common except in instances of secondary OA (e.g., associated with acromegaly, hemochromatosis).

OA of the first CMC joints (trapeziometacarpal and trapezioscapoid) is common. There is a tendency for osteophytes to develop on the distal ulnar surface of the trapezoid, associated with radial subluxation of the proximal head of the first metacarpal. This gives the base of the thumb a “squared” or “knobby” clinical appearance (see Fig. 173.3). In contrast to PIP and DIP involvement, this deviation is commonly associated with pain and disability. The severity of hand OA is associated with reduced grip and pinch strength.³⁹ Pain at the base of the thumb may be on the radial side of the joint or on the palmar aspect of the joint at the proximal insertion of the thenar muscles.

Although the course of hand OA is usually insidious, in a subset of these patients the disease may have an aggressive and destructive course. This has suggested a classification of hand OA into nodal (noninflammatory) OA and erosive interphalangeal (inflammatory) OA. Debate continues as to whether nodal and erosive interphalangeal arthritis are separate entities or part of the spectrum of the same condition. On occasion, the evolution of interphalangeal OA may be indistinguishable from early-onset rheumatoid arthritis or psoriatic arthritis.

Hips

Patients with hip OA most often have groin or anterior hip pain that radiates into the thigh. Pain is associated with early ambulation and weight bearing and is lessened or relieved by rest. Examination most often reveals difficulty rising from a seated position, altered gait favoring the arthritic hip, and reduced range of motion on examination, with pain on motion, particularly internal rotation.

Hip OA is most commonly associated with an insidious onset of pain (malum coxae senilis, coxarthropathy). Pain is noted on weight-bearing activity and must be distinguished from referred lumbar pain. Both lumbar

Fig. 173.4 Osteoarthritis of the hips. Severe osteoarthritis secondary to pelvic Paget disease causes medial and axial migration of the femoral heads into the acetabuli, resulting in hip flexion contractures. The patient stands with a bent-forward posture that is apparent from a lateral (a) or anterior (b) view.

spine and hip OA may be painful when the patient rises from a seated or reclined position and during early ambulation. Pain from lumbar stenosis often has its onset after ambulation for a distance and, because of radiation to the thighs, is more suggestive of claudication (pseudoclaudication). More severe hip OA may be painful at all times, even at rest. Pain is usually localized to the groin or medial thigh but may be lateral, suggesting (and associated with) trochanteric bursitis and/or meralgia paresthetica. Hip OA is associated with an antalgic gait, one in which the patient overshifts the weight while walking to reduce the pain. There is loss of extension that often goes unnoticed. Loss of hip flexion and rotation is noticed by the patient because of difficulty when attempting to put on socks or shoes. When severe, a flexion contracture is associated with a prominent limp (Fig. 173.4). Severe OA of the hip is associated with a loss of internal rotation (less than 15 degrees) on examination.⁴⁰ The involved hip is flexed, externally rotated, and adducted. The Trendelenburg sign may be present: standing on the involved extremity leads to a drop in the contralateral hip from weakening of the ipsilateral hip abductors. Another late sign is shortening of the extremity as the femoral head migrates superiorly and axially into the acetabulum, in association with a flexion contracture of the hip.

Most hip OA is slowly progressive. However, there is a subset of patients, estimated at 10%, with a rapidly progressive form of hip OA that evolves over a few months. Unfortunately, at this time, there is no particular clinical characteristic or set of characteristics that at onset can separate those with rapidly progressive OA from those with the less aggressive forms.

Hip pain must be distinguished from referred lumbar spine pain, trochanteric bursitis, meralgia paresthetica, avascular necrosis, transient osteoporosis of the hip, femoral/acetabular impingement, torn labrum, and nondisplaced hip fractures, which can be difficult to detect on routine radiography.

Knee

Patients often experience an insidious onset of pain about the knee, particularly with weight bearing and stair climbing (gonarthrosis). The patient may have noticed knee swelling and/or varus/valgus deformity. Examination sometimes reveals swelling with loss of the usual crease in the skin and soft tissues over the inner (null) facet between the patella and the

Fig. 173.5 Osteoarthritis of the knee. This morbidly obese woman has an enlarged knee with a flexion contracture. Lack of mobility is reflected by her use of a wheelchair. Synovial effusion of the knee is difficult to detect by inspection or palpation in a knee distal to a thigh of this size.

femoral condyle, in addition to a bulging suprapatellar sac. When present, the effusions are usually cool to palpation. There may be warmth and tenderness, but redness is uncommon. Reduced function may be due to a flexion contracture (also known as *extension lag*, the inability to extend to 0 degrees) and sometimes an extension contracture (loss of flexion with inability to flex to 115 degrees) (Fig. 173.5). The flexion contracture is noticeable due to a prominent limp. The extension contracture causes difficulty rising from a seated position. There is often tenderness of the anserine bursa and crepitus on active motion of the knee.

Crepitus on motion is best detected on active joint motion. Occasionally distention of the popliteal semitendinosus bursa (popliteal or Baker cyst) may be present. There may also be herniation or rupture of the bursa

into the thigh or leg (herniated or ruptured popliteal cyst) suggestive of thrombophlebitis (pseudothrombophlebitis syndrome). Marginal osteophytes, intrasynovial loose bodies (joint mice), or moveable bodies (osteochondromas) may be palpable. Medial narrowing of the joint space (radiographic interbone distance) may lead to or aggravate a varus deformity, whereas lateral joint space narrowing may lead to a valgus deformity. Varus deformity with valgus deformity of the contralateral knee gives the patient a “wind-swept” appearance. There is often associated quadriceps weakness and atrophy.

Knee OA may be associated with pain at the distal medial joint margin (anserine bursitis at the insertion on the pes anserinus of the tibia). This is particularly common in the elderly with significant varus deformity. Both varus malalignment and standing balance correlate with the severity of knee OA.⁴¹ Knee OA also has been associated with quadriceps weakness, reduced knee proprioception, and increased postural sway.⁴² When present, reduced proprioception occurred in the contralateral knee.⁴³ It was thought that both pain and muscle weakness influence postural sway. Although quadriceps strength was significantly lower in patients with OA of the medial compartment of the knee, the hip adductor muscles were actually stronger, perhaps in compensation for the varus deformity.⁴⁴

Meniscal tears may be difficult to determine on physical examination of patients with knee OA. A positive McMurray test is the only true predictor of an unstable meniscal tear.⁴⁵ Cruciate ligament deficiency can be detected by an anterior or posterior drawer sign. In presentations with acute hemarthrosis, cruciate ligament injury should be suspected.

Adult patellofemoral OA is not commonly symptomatic. Anterior knee pain is aggravated by sitting in low chairs (e.g., at movie theaters) and can be precipitated by pressure with mediolateral movement of the patella in the intercondylar groove (patellar apprehension or grind test). There is a variant of patellofemoral OA in young women (chondromalacia patellae) that produces anterior knee pain. Symptoms from patellofemoral OA are usually self-limiting, resolving in a period of several months; some patients experience improvement after a course of patellar taping by a physiotherapist. However, there is a small subset of adults with patellofemoral OA who have significant and persistent pain with disability.⁴⁶

OA of the knee may be associated with varying degrees of subchondral spontaneous osteonecrosis of the knee. This is suspected in patients with a rather abrupt onset of particularly severe pain refractory to the usual therapy and is usually due to a subchondral insufficiency fracture. In early phases, it is best detected by magnetic resonance imaging. Uncommonly, there is a destructive arthropathy associated with a variety of calcium crystals.

Ankle

Talonavicular and subtalar joint OA is usually secondary to trauma with or without ligamentous damage or to an old ankle fracture. Patients complain of ankle pain on weight bearing. Examination reveals swelling of the ankle that must be distinguished from a variety of conditions, such as Achilles bursitis, plantar fasciitis, talocalcaneal coalition, painful os trigonum, posterior tibial tendinitis, and pedal edema.

Feet

Patients with OA of the feet most often present with pain of the first metatarsophalangeal (MTP) joint, particularly with walking. Examination commonly reveals an enlarged joint, with medial subluxation and lateral deviation of the big toe (bunion deformity). There are sometimes signs of inflammation over the involved joint, with tenderness and loss of dorsiflexion. Abnormalities of additional toes are common.

The typical pattern of involvement of the feet includes the first MTP joint, commonly called the *bunion joint* (hallux valgus) (Fig. 173.6). The joint enlarges medially, with a lateral drift of the first toe, which often overlaps with the second toe.

There may be loss of function of the first MTP (hallux rigidus), usually occurring without drifting of the great toe but limiting toe-off with ambulation. In this condition, the enlargement is usually dorsal.

There is often painful and tender swelling of foot joints. Associated contractures of additional toes (cock-up deformity) with loss of plantar fat pads are often seen. Disabling pain on ambulation may ensue. Pes planus, with relaxation of the transtarsal ligament and a pronator forefoot deformity, aggravates the symptoms. The patient may find it difficult to wear certain types of shoes, particularly those with high heels.

The talonavicular joint is at the pinnacle of the arch of the foot and is particularly prone to OA in the dorsal portion of the joint. This form of OA is aggravated by pes planus. Midfoot OA is associated with a short first metatarsal and/or a long second metatarsal bone.⁴⁷

Fig. 173.6 Metatarsophalangeal (MTP) and interphalangeal osteoarthritis of the feet. There is bilateral enlargement of the first MTP joint, with medial subluxation of the phalanx. Flexion contraction of toes (particularly of the right second digit), with subluxation of the MTP, has caused an associated callus over the dorsum of the proximal interphalangeal joint. The right third digit is subluxed under the second digit. There is relaxation of the transtarsal ligament, with medial subluxation of the MTP and bony enlargement of the fifth MTP joints (tailor bunion, bunionette).

EVALUATION

Laboratory tests

There are no laboratory tests that are diagnostic for OA. Low-grade inflammation in OA can be detected by measurement of serum acute-phase reactants, such as C-reactive protein. Synovial fluid and serum markers of OA are being investigated as tools to detect the presence of OA or to predict or detect disease progression.^{48,49} To date, however, no individual marker has accomplished either of these goals, and a combination of markers may be needed.

Synovial fluid from patients with OA is usually clear and colorless or with a slight yellow tinge. The polymorphonuclear leukocyte content is usually less than 2000 cells/mL. Inflammatory synovial effusions may occur in the presence of calcium crystals. Synovial fluid from a DIP cyst is often jellylike and contains large polymorphonuclear leukocytes with several refractile inclusion cysts. Synovial fluid from a joint with osteochondromatosis is often very viscous and relatively acellular. It should be pointed out that normal synovial fluid contains fewer than 100 cells/mL; hence the modest increase in synovial fluid leukocytes in OA is reflective of low-grade inflammation.

Crystals may be present in as many as 70% of synovial fluid specimens from patients with OA.⁵⁰ Although all calcium crystals have been shown to precipitate inflammation, the relationship of hydroxyapatite and several forms of basic calcium phosphate to the synovitis that is present in patients is not well established.

Imaging

A detailed description of the imaging characteristics of OA is given in Chapter 177.

CONCLUSION

Symptomatic OA is common and affects a large segment of the population, particularly women older than 50 years of age. Although OA can affect nearly any joint in the body, OA of the weight-bearing joints leads to the most disabling symptoms. Hand, hip, and knee OA can cause significant morbidity, impairment of physical activity, physical disability, and increased all-cause mortality. Pain is the most common complaint that causes the patient to seek a physician's assistance. Examination often reveals loss of function and may uncover some of the signs of inflammation. The findings on careful history taking and physical examination should lead to the formulation of an individualized program of therapy.

Animal models of osteoarthritis

■ JEAN-PIERRE PELLETIER ■ MOHIT KAPOOR ■ JOHANNE MARTEL-PELLETIER

EXPERIMENTAL ANIMAL MODELS THAT REPRODUCE THE CHANGES OBSERVED IN NATURALLY OCCURRING OSTEOARTHRITIS ARE EXTREMELY VALUABLE FOR THE FOLLOWING REASONS:

- They allow the study of alterations in a timewise fashion and permit sequential evaluation of the disease lesions.
- They facilitate the understanding of osteoarthritis pain mechanisms and the discovery of novel therapeutic approaches.
- They permit the evaluation of disease-modifying osteoarthritis drug treatment effects, using noninvasive joint imaging such as magnetic resonance imaging.

LARGER ANIMAL MODELS OF OSTEOARTHRITIS PROVIDE THE FOLLOWING:

- Larger tissue samples allowing extensive exploration of the biochemical and molecular mechanisms of the disease
- A more global exploration of the effects of drugs on different osteoarthritis pathways, which includes clinical evaluation, quantification of the disease changes by imaging, and morphologic examination
- Translational data for treatment dosages and route of administration because they better mimic human clinical conditions

INTRODUCTION

Osteoarthritis (OA) is the most common form of arthritis. The joint tissues are the sites of abnormal pathophysiologic pathways responsible for the development and progression of OA; further details are provided in Chapter 175 and elsewhere in this book. The evolution of structural changes in OA occurs over an extended period, which makes it very difficult to study the etiopathogenesis of the disease in humans. Experimental models capable of reproducing the changes that occur in OA can be valuable, especially for studying these alterations in a timewise fashion with the possibility of sequential evaluation of the disease lesions. In recent years efforts have been under way to standardize the outcomes of OA animal models.¹ Another dimension of OA is the pain, which is the most prominent clinical symptom of this disease. An unresolved issue in OA pain research is the lack of understanding of the mechanisms responsible for its induction and maintenance. There is therefore an urgent need to improve the characterization of animal models to facilitate the discovery of novel approaches to pain relief for OA patients.

This chapter concentrates on the experimental OA models that have been most commonly used for the identification and study of therapeutic targets, the development of disease-modifying osteoarthritis drugs and agents (DMOADs), and the treatment of pain. These models are reviewed and their similarities to the natural disease in humans are examined. This review is arbitrarily divided according to the size of the animals used: large, medium, and small. Not all experimental animal models used and studies done to date can be reviewed due to chapter size limitations.

LARGE ANIMAL MODELS

Among the large animal models of OA, one of the most studied models of induced OA is the canine anterior cruciate ligament transection (ACLT).

This model has been extensively studied morphologically and pathophysiologically and has demonstrated interesting similarities to the human disease. It is the model most commonly used to test the efficacy of DMOADs. Another canine surgical model is the groove model, which is more sensitive for therapy aimed at cartilage defects and more appropriate for studies examining cartilage protection and repair. Another large animal model of interest is the sheep meniscectomy model, which has been used in clinical investigations of a number of DMOADs. Large animal models of spontaneous disease include the monkey and dog models; however, the former is not widely used.

Induced osteoarthritis models**Dog****Anterior cruciate ligament transection model**

The traumatic rupture of the anterior cruciate ligament (ACL) is a frequent musculoskeletal disorder, both in dogs and in humans, which has been demonstrated to be a significant risk factor for the development of knee OA. In the first dog model to be introduced, OA was induced by experimentally transecting the ACL in normal mongrels using a closed surgical procedure (stab incision).² A variant of this model involves use of an open surgical procedure.³ This latter model was further modified by performing a dorsal root ganglionectomy before the surgery to accelerate the development of structural lesions by creating a neuropathic arthropathy.⁴

In the dog ACLT model, the cartilage biology and morphologic, histologic, and matrix biochemical changes were reported to be analogous to those observed in the naturally occurring disease. In-depth analyses have been done of the metabolic and structural changes in the articular cartilage, the synovial membrane, and the subchondral bone. The macroscopic changes in the cartilage are first seen as a yellowish discoloration of the surfaces, particularly in the weight-bearing areas of the condyles and plateaus, with some cartilage swelling seen in the adjacent area in the early phase of the disease. These early lesions lead to fibrillation and a progressive erosion of the cartilage down to the subchondral bone over the months following the surgery. Several factors can influence the rate of progression of these lesions in this dog model, such as weight and amount and type of exercise. From a histologic point of view, additional changes include loss of proteoglycan content in the cartilage and hypertrophy and cloning of chondrocytes, which eventually progresses to hypocellularity of the tissue in the more severe stages. Also observed in the later stages is a thinning of the calcified cartilage layer and invasion of the tidemark by blood vessels.

The OA cartilage lesions are associated with an increased level of proteoglycan and type II collagen synthesis with a breakdown of the collagen network and reduced aggrecan size. An increase in the level of proteases was also found, including matrix metalloproteinase-1 (MMP-1), MMP-3, and MMP-13, as well as cathepsin K, ADAMTS4, and ADAMTS5.⁵ The upregulation of MMP synthesis was mediated by activation of several key intracellular signaling pathways in which the mitogen-activated protein kinases (MAPKs) play an important role. The increased level of the inducible form of nitric oxide synthase (iNOS) induces the production of nitric oxide, which in turn mediates chondrocyte apoptosis, cartilage degradation, and synovial inflammation. There is also an increase in local production of leukotrienes. More specifically, leukotriene B₄ has been found to be among the factors that mediate the increased levels of MMPs, ADAMTS, and iNOS in cartilage and interleukin-1 β (IL-1 β) in the synovium.⁶

In the dog ACLT model, synovitis is present at all times following surgery and is of significant severity. In the early stages, it is likely to originate from the postsurgical reaction and intraarticular bleeding, whereas in the long term it would seem to be part of the global disease process. Histologically, the main changes are hyperplasia and hypertrophy of the lining cells with

Fig. 174.1 Comparative assessment of cartilage lesions by magnetic resonance imaging (MRI) and macroscopic grading in an osteoarthritic (OA) dog knee. The technology of this three-dimensional (3D) reconstruction of femoral condyle and tibial plateau cartilage thickness from MRI data acquisition can precisely detect and quantify the severity of the macroscopic cartilage lesions, as shown in this OA knee 26 weeks after anterior cruciate ligament transection. A, anterior; L, lateral; M, medial; P, posterior. Circles indicate areas of cartilage lesions corresponding to the macroscopic findings. (Modified from Boileau C, Martel-Pelletier J, Abram F, et al. Magnetic resonance imaging can accurately assess the long-term progression of knee structural changes in experimental dog OA. *Ann Rheum Dis* 2008;67:926-32.)

mononuclear cell infiltrate of the sublining tissue. This diseased tissue is also the site of the production of cytokines, inflammatory mediators, and proteases that contribute to cartilage degradation.

In the first few months following ACLT, the subchondral bone is the site of intense remodeling, predominantly resorptive in nature, with thinning of the subchondral plate and an increase in the trabecular space. There is an abundance of bone resorption units associated with an increase in the local production of bone resorption biomarkers such as MMP-13, cathepsin K, and urokinase.

The cartilage changes were shown to evolve over a long period, and a progression up to 4 years after surgery was reported.⁷ A recent study using quantitative magnetic resonance imaging (MRI), which documented cartilage changes up to 26 weeks following the surgery, supports the previous findings (Fig. 174.1).⁸ Moreover, the bone marrow lesions were found to increase in size over time and to be topographically associated with cartilage lesions.⁸ These findings have raised the possibility that the bone changes may play a role in the genesis of cartilage lesions.

One of the typical behavioral features of this dog model is a variable lameness of the affected limb. The fact that the lameness correlates with a reduction in the subchondral bone volume in early OA is strongly suggestive of a relationship between subchondral bone changes and pathologic articular cartilage. It also was shown that the functional impairment correlated with structural changes in ACLT dogs and that bone marrow lesions, cartilage defects, osteophytes, and joint effusion size impair the limb remission, but that cartilage volume loss and meniscal alterations are related more to excessive mechanical stress.

In this model, lameness is interpreted and referred to as a behavioral correlate of pain in the joint. For the assessment of a given treatment, it is suggested that gait analysis be used concomitantly with other functional methods such as functional activity and limitation-of-activities measures.

Indeed, at short intervals after surgery the force platform analysis alone is most likely confounded by structural effects. However, at longer intervals after surgery the force platform analysis appears to be more accurate because the relative contributions of structural effects versus direct pain effects may be different as the joint damage progresses over time.

Groove model

The groove model, a canine model of joint degeneration with much less severe joint damage,⁹ results from surgically applied damage to the weight-bearing cartilage of the condyles combined with forced loading. Recently, a bilateral version (damage of the lateral and medial condyles) of this model was developed and characterized, in which the features appeared to be slightly more severe than those in the unilateral model.¹⁰ It is suggested that these models be created via arthroscopy to limit the confounding effects of arthrotomy. In the unilateral model, histologic and histochemical examinations revealed pathologic cartilage predominantly in the medial compartment (femur and tibia), which was often mild. Although this model showed osteophyte formation and cartilage damage in which there was an increased synthesis of proteoglycans, decreased retention of the newly formed proteoglycans, and increased release of proteoglycans resulting in decreased proteoglycan content, these are much less pronounced than in the ACLT model. Interestingly, in this model the degenerative cartilage changes are progressive, whereas synovial inflammation diminishes over time.⁹ There is a discrepancy in the literature with regard to whether or not there is thinning of the subchondral bone in the groove model. These contradictory findings could be attributed to the difference in the groove models used.

Sheep and goats

Sheep and, to a lesser extent, goats have been used to study the pathogenesis of OA and the effect of treatment with potential DMOADs. These species

offer the advantage of being large animals with biomechanics closer to that of humans. As with the dog, the size of the sheep's joints allows outcomes to be measured in numerous ways, including routine arthrocentesis and synovial fluid collection; imaging such as radiography, computed tomography, and MRI; as well as gait analysis, arthroscopic joint examination, topographic evaluation of lesions, and histologic, biochemical, and molecular analyses.

The main OA models in sheep involve surgical induction of OA, with the most common involving partial or total meniscectomy. The sheep ACLT model has been reported as an OA model but is not commonly used, and the surgery alone appears to induce very limited or mild cartilage damage in this species.¹¹ Some investigators have used ACLT combined with medial meniscectomy.

The most frequently used sheep model is the total unilateral medial and/or lateral meniscectomy model. The lesions in the lateral meniscectomy model are generally more severe than those in the medial meniscectomy model. The development of cartilage lesions is progressive over time following surgery. Mild lesions are observed at 3 months after surgery and significant changes are seen between 6 and 9 months, which progress to full-cartilage-thickness erosion by 24 months. Cartilage lesions are associated with other joint structural changes, such as osteophytes and subchondral bone remodeling. The histologic cartilage changes are similar to those reported in the OA dog models. There is also a thickening of the subchondral cancellous bone with an increase in bone mineral density. Exercise involving weight bearing accelerates the rate of progression of lesions. The biochemical cartilage changes, including a reduction in the level of matrix macromolecules such as aggrecan, are associated with a preferential increase in the synthesis of dermatan sulfate proteoglycans (decorin), particularly in zones of cartilage subjected to high mechanical stress. The release of aggrecan fragments from the cartilage correlates with increased levels of active MMPs found in the tissue. The synovial membrane also undergoes histologic changes characterized by hyperplasia but without evidence of subsynovial tissue inflammation. The characterization of pain responses in this model is largely lacking.

Spontaneous osteoarthritis models

Monkey

Characterization of spontaneous OA has been performed in two nonhuman primates: rhesus¹² and cynomolgus¹³ macaques. In the former model, the prevalence and severity of OA increased with age and, in females, with parity. Both models exhibit OA lesions morphologically similar to those seen in humans. In the rhesus, features included a decrease in the levels of glycosaminoglycans in old animals with OA compared with age-matched normal animals and decrease in collagen with severity of OA. In the cynomolgus, lesions are most severe in the medial tibia and are characterized by fibrillation, clefting, and loss of articular cartilage, with concomitant marked thickening of the underlying subchondral bone. Interestingly, bone changes were more common and severe than cartilage changes and morphologically appeared to precede the cartilage changes.¹³ Compositional analysis of the mineralized plate beneath the articular cartilage in OA showed thickened and overmineralized calcified cartilage and subchondral bone. To the authors' knowledge, no reports on the effects of drugs on OA progression in these models have been published.

With regard to OA pain, although some of the older animals affected with OA walked with an altered gait similar to limping, which indicates that they experienced symptomatic disease, there have been no reports to objectively quantify the OA-associated pain.

Dog

Both the clinical expression and pathogenesis of naturally occurring canine hip dysplasia and OA are considered analogous to those of the human diseases. Progressive and degenerative canine OA causes notable signs of pain, such as lameness and physical disability. Pain and lameness may be acute or chronic, and OA may occur in any joint in dogs.¹⁴

Certain breeds may be predisposed to primary idiopathic OA. For the most part, canine OA is considered secondary to acquired or congenital musculoskeletal disorders. Concomitant factors such as aging and obesity likely accelerate progression. However, mechanical factors appear to predominate in the etiopathogenesis of canine spontaneous OA. Surveys in the United States suggested that approximately 20% to 30% of the canine population over 1 year of age suffers from OA.¹⁵ In certain breeds, the prevalence of hip dysplasia ranged from 41% to 73%.¹⁶

A diagnosis of OA is based on clinical signs, physical examinations, radiographs, and synovial fluid analyses. Some subjective (client-based) tools for the measurement of OA-related pain outcome in dogs have been

validated, and as an objective evaluation, gait analysis using a force platform provides a noninvasive assessment of lameness. The trotting gait was more sensitive than the walking gait for differentiation of dogs with low-grade hind limb lameness. Also used to decouple gait mechanics from pain originating in other organs, such as the muscles or skeleton, is intraarticular anesthetic injection. Gait analysis successfully served to detect acute pain in these animals, but other standardized pain assessment instruments for dogs have been developed and validated.¹⁷⁻²⁰ An advantage of these assessments is that they report the owner's evaluation of the dog's pain over a period of time, which increases the sensitivity of functional outcome measures.

Sheep

Spontaneous OA, although rare in sheep, may occur in the unprotected region of the tibias, but this sheep model has not been reported as a viable model.

Large animal model limitations

The OA morphologic, biochemical, and structural changes in the dog ACLT and the sheep meniscectomy models reveal several similarities to the natural disease. The dog groove model creates immediate cartilage injury and loss with resultant incongruity and changes in load-bearing articulation of the joint that can be a potential model for knee injuries by a traumatic force. This model might be valuable for studies looking specifically at OA secondary to previous articular cartilage defects. However, the pain is also milder, which may make demonstrating effects of drugs on behavior difficult.

The dog and sheep models allow evaluation of the progression of structural changes through several types of imaging technologies, and the joint size can be used for a large number of analyses to study the effect of DMOAD interventions on joint structure as well as disease pathways. However, because sheep are ruminants rather than monogastrics, the bioavailability of oral therapies may require additional validation. These models also permit the possibility of performing gait analyses as a surrogate marker of pain and functional ability.

The nonhuman primate models of spontaneous OA are interesting because of the availability of age-matched controls, tissue with early OA, joints large enough for radiologic and other imaging technologies, and morphologic and biochemical studies. The drawbacks are their relatively long life spans, uncontrolled environmental factors, and, most importantly, ethical concerns.

In conclusion, interesting information about the OA disease process has been generated by studies using large animal models. The striking similarities in the disease pathways between these surgically induced OA models and the human natural disease, the parameters that can be evaluated in these models, and their use in DMOAD studies (Table 174.1) makes these models—especially the canine ACLT model—quite attractive. In idiopathic OA, various etiologic factors join forces to bring about the structural and molecular changes typical of the disease, although it is likely that some factors that contribute to the natural human disease may not have an effect in these models.

With regard to the disease-modifying effects of certain OA drugs and agents in these models and in clinical trials in humans, a good correlation has been shown, in general, for both positive and negative findings. Obvious limitations of the preclinical studies arise from the variability in experimental protocols from one study to another. Moreover, the level of effectiveness of treatment is rather difficult to compare between human and animal model studies due to the methodologic differences. Most preclinical studies have been of short duration, which is an obvious additional limitation.

With regard to pain evaluation, the major limitation is the predictive value of the drug efficacy assessment, because there is a need to further develop and validate pain assessment techniques and improve the predictive validity of the evaluation instruments.

MEDIUM-SIZED ANIMAL MODELS

Among the intermediate-sized animals used in OA research, the rabbit has been the most popular. Rabbit models of OA include those in which OA is created chemically, by repetitive trauma, by patellar impact, and after surgical alteration of joint mechanics. The two most studied rabbit models are the ACLT and partial meniscectomy models. With regard to the feline models, the most employed induced model is the ACLT model. Spontaneous OA models have also been reported in these two species, with the cat being the most studied.

TABLE 174.1

Summary of drugs/agents evaluated *in vivo* in some of the large animal models of osteoarthritis (OA) for disease-modifying effects

Model	Tested drug	Effect of treatment
Dog ACLT	Corticosteroids	Reduced OA cartilage degradation and osteophyte formation
	NSAIDs	Protected against (licofelone, tenidap) or accelerated (indomethacin) OA cartilage degradation
	iNOS inhibitor	Reduced OA cartilage degradation and synovial inflammation
	IL-1Ra	Reduced OA cartilage degradation
	Diacerein	Reduced OA progression
	Doxycycline	Reduced OA development and progression
	Bisphosphonate (NE-10035)	Reduced subchondral bone turnover; no effect on osteophytes or cartilage degradation
	Bisphosphonate (tiludronate)	Reduced OA development and progression and subchondral bone changes
	Calcitonin	Reduced cartilage damage, protected against cartilage degradation and subchondral bone changes
	PPAR- γ agonist (pioglitazone)	Protected against development of OA lesions
	Hyaluronan	No effects on OA progression
	Avocado and soya unsaponifiables	Reduced OA cartilage lesion development and subchondral bone remodeling
	<i>Brachytemma calycinum</i> D. Don	Reduced OA cartilage lesion development
	Strontium ranelate	Reduced OA cartilage lesion progression, improved subchondral bone remodeling
Sheep	Hyaluronan	Reduced OA progression, improved subchondral bone remodeling
	Avocado and soya unsaponifiables	Reduced OA progression, prevented subchondral bone remodeling
	Diacerein	Improved OA cartilage lesions and subchondral bone parameters in lesional areas
	Chondrogenic-induced bone marrow stem cells	Retarded progression of OA

ACLT, anterior cruciate ligament transection; IL-1Ra, interleukin-1 receptor antagonist; iNOS, induced nitric oxide synthase; NSAIDs, nonsteroidal antiinflammatory drugs; PPAR- γ , peroxisome proliferator-activated receptor- γ .

Induced osteoarthritis models

Rabbit

New Zealand white rabbits are frequently used medium-sized models of OA, which include the hemi meniscectomy or partial meniscectomy model. Following an incisional exposure to the medial compartment of the stifle (knee), the anterior horn of the meniscus is freed from its lateral attachment on the tibia. A small portion is removed from the lateral part of the anterior horn of the freed meniscus. There is relatively little bleeding in contrast with the ACLT technique. Once the wound is closed, the freed meniscus appears to act similarly to a torn meniscus in humans, altering joint mechanics and inducing a traumatic model of OA.

The ACLT model requires open surgery, and bleeding is common. The procedure is similar to that in the dog ACLT model (open surgery). After the procedure, OA develops insidiously over a period of 6 to 12 weeks; 8 weeks is suggested for early OA and 16 weeks for late OA.²¹ To characterize changes, the operated joint is often compared with the contralateral stifle or with a joint undergoing sham surgery. A few studies have employed models in which both stifles were operated on, with one used as the control for the treated contralateral joint.

Studies of the stifle joints have included examination of gross and microscopic anatomy, as well as synovial fluid and synovium assessment. The cartilage lesion depth and size can be measured and osteophytes assessed. Microscopic examination can evaluate proteoglycan content and cartilage changes. As in the large models of induced OA, abnormalities have been demonstrated in the synovium and cartilage. The cartilage and the joint can be studied using gait analysis,²² biochemical methods, and MRI.²³ Data showed that the ACLT procedure tended to induce lesions on the postero-medial aspects of the joint, particularly on the covered areas of the tibia. This suggests that these cartilage areas are the most prone to change and hence are the specific areas of the joint to be studied.²⁴ Findings from 4 and 8 weeks after ACLT surgery revealed that the expression of MMP-1 in synovium lagged behind its expression in cartilage, which suggests that the pathologic process was initiated in the cartilage. The rabbit meniscectomy model was also used to measure pain and demonstrated decreased weight bearing by the ipsilateral limb over time.²²

Cat

There exists an ACLT model for the cat. Unlike in the canine model, the ground reaction forces and the hind limb kinematics revert to near-presurgical patterns within 5 months after surgery. Early adaptive responses following ACLT appear to be associated with a reduction in the mechanical loading, but a continued progression toward OA occurs despite almost normal knee mechanics at 1 year following surgery. At 12 to 16 weeks after ACLT, there is an increase in the articular cartilage,²⁵ and long-term experiments revealed cartilage degradation and formation of osteophytes at the

joint margins consistent with the development of OA. Specifically, there was focal loss of articular cartilage on the medial tibia, the condyles, and the retropatellar surface. The areas where the cartilage was not completely eroded away showed hypertrophic cartilage with surface lesions, and loss of proteoglycan in the superficial zone. The menisci appeared fibrillated and exhibited tears, particularly in the medial plateau. The synovial inflammation associated with ACLT returned to normal approximately 1 month after surgery.²⁶ Concurrent with the articular cartilage degeneration, there was a decrease in cancellous bone mass and subchondral plate thickness in both medial and lateral compartments as early as 16 weeks after surgery, and these changes became more pronounced in the development of the disease 5 years after surgery.²⁷

Spontaneous osteoarthritis models

Rabbit

Naturally occurring OA in the rabbit has been reported recently.²⁸ Data showed that the presence and severity of OA were significantly influenced by both age and body weight but not by gender. Hind limb joints, including the knee and hip, were most commonly affected. OA was detected in radiographs from about 40% of the studied domestic rabbits. Of the affected rabbits, 37% had two or more pairs of joints involved, and 13% had three or more pairs affected. There was a significant association between rabbit breed and the presence of OA, with dwarf rabbit breeds having a lower incidence than the 12 nondwarf breeds. No differences in OA prevalence were found among the nondwarf breeds.

Cat

Until this decade, little attention was paid to spontaneous OA in cats. Spontaneous OA has been shown to occur in cats, with the prevalence increasing dramatically with age.^{29,30} In cats older than 6 years, OA was found in at least one joint in 61% of animals and in more than one joint in 48%; in cats older than 14 years, OA was found in at least one joint in 82%.³¹ Advancing age, but not obesity, appears to be the main risk factor for both increasing prevalence and increasing severity of feline OA, which is most frequently seen in the elbow, hip, and stifle joints. Older cats exhibit difficulties with mobility, and it is common to observe radiographic evidence of OA in multiple joints of aged cats.

Although OA is very common in older cats, it is poorly diagnosed in clinical practices. This may be due to the poor correlation between orthopedic evaluation and severity of OA structural changes and/or the lack of validated chronic pain assessment tools for cats.³⁰ In cats, the disease seems to be constitutional rather than the end stage of a variety of developmental diseases, as seen in dogs. The diagnosis can be based on radiography and a combination of history, owner observations, lameness, and orthopedic examination findings. A recent study using MRI demonstrated a good

correlation between functional and structural evaluations of OA lesions in cats.³² More work is being done to develop validated owner questionnaires that rely on client-specific outcome measures, using items such as walking, running, jumping up and down, climbing stairs, playing with toys, and so on. For pain evaluation, gait analysis, accelerometry techniques, the von Frey withdrawal threshold (assessing allodynia/hyperalgesia), and collar-mounted accelerometers to measure activity levels were shown to be capable of characterizing OA-associated pain outcomes in cats.³²

Medium-sized animal model limitations

Advantages of the rabbit models include facility of handling, inexpensive purchase and maintenance costs, ease of surgery, relatively small cage requirements, and rapid development of OA. Disadvantages are the small volume of cartilage that is removed from the joint, which often requires pooling of specimens; the anatomic differences between rabbit and human cartilage and subchondral bone; the difficulty in mobilizing rabbits; and the number of animals needed for any given experiment. In contrast with the human joint, rabbit cartilage is normally thinner and more cellular, the subchondral bone is stiffer, and the epiphyses are not closed unless older rabbits are selected for study. This is also important for the spontaneous OA rabbit model, of which a downside is the wide variability in the age at which bone maturity is achieved, because even 9- to 10-month-old rabbits can have open physes or growth plates in the distal femur and proximal tibia.

The rabbit has proven to be an easy model in which to explore potential DMOAD therapies for OA. However, several agents that were promising in the rabbit models have been disappointing in humans. The discrepancies in the findings of the therapeutic effects of these agents between the rabbit models and human disease are not fully explained. It could be that the therapeutic agent is not effective in humans or there may be problems with dosing. It could also be that this medium-sized model reflects only subsets of human OA, not the full spectrum of the human disease. Despite these drawbacks, until an effective therapy is available, the rabbit models of OA will continue to be useful in preclinical studies.

Cat models of both induced and spontaneous OA may offer advantages similar to those of the rabbit. However, although some histologic features were reported in the induced OA model, biochemical knowledge of OA articular tissues is lacking for both the induced and spontaneous OA models. Furthermore, in the spontaneous OA model, the recognition of chronic arthritic pain is a major challenge compared with other species because, instead of developing lameness, cats use behavioral strategies to disguise pain. A lack of familiarity with feline joint radiographs means that radiographic identification of OA in cats can also be problematic. At present, this model serves mainly for pain assessment and documentation of response to analgesic treatment. However, although gait analysis appears to have potential and accelerometry could be used as a complementary approach providing objective assessment of motor activity, validated, precise, and sensitive techniques to measure clinical outcomes in this OA model are still in their infancy. In addition, species-specific differences in pharmacology in cats further complicate translational research.

SMALL ANIMAL MODELS

Many small animal models of OA have been developed, which generally involve the mouse, the rat, or the guinea pig. Some are models of spontaneous OA, whereas in others OA is induced through various interventions. In contrast to the large and medium-sized animal models in which induction is almost always performed by mechanical means, in small animals it can also be induced by biochemical joint alterations. Small animal models, which can reproduce important features of human OA including cartilage destruction, osteophyte formation, and synovial inflammation, have been valuable research tools for exploring the pathophysiology and treatment of OA. They allow for the evaluation of various catabolic and anabolic pathways that are highly relevant to the disease process. For example, some models such as the STR/ort mouse have helped to demonstrate the cleavage site of aggrecan by proteases. Small animal models are most useful for gaining insight into many aspects of the pathophysiology of OA because they provide the unique possibility of performing studies in a large number of animals aimed at a comprehensive evaluation of the disease process. Some imaging technologies for small animals have also been developed that can be used to assess disease progression and quantify structural changes.^{33,34}

This section summarizes some of the different possibilities that these small animal models of OA offer in exploring the disease process.

Induced osteoarthritis models

In small animals, OA can be induced, particularly in the knee joint, following different types of interventions that produce metabolic and/or mechanical changes in the joint and create OA-like modifications in the cartilage, synovium, and subchondral bone. The most common induced models are produced by intraarticular injections of chemicals or proteases, by surgery, or by genetic modification.

Intraarticular injections

In one of the intraarticular knee injection models OA is induced by monoiodoacetate (MIA), an inhibitor of glycosyltransferases.³⁵ MIA injection induces alterations in chondrocyte biology in contrast to the mechanical models, in which joint instability is created. This model has been induced mainly in the rat, mouse, and guinea pig. The severity of joint alterations from MIA injection is dose dependent, and MIA generates pain and structural and biochemical alterations associated with OA. There is considerable variation in the dose and volume used in preclinical studies to induce OA in the MIA model (1 to 4.8 mg). In cartilage, the changes are characterized by proteoglycan depletion and degradation in which aggrecanase- and MMP-generated catabolic epitopes have been detected. The cartilage lesions develop rapidly following MIA injection. The classic duration for this model is 28 to 30 days, but it has been studied for up to 56 days.³⁵ Cartilage surface irregularities are present 7 days after injection, and the lesions reach maximal intensity between 14 and 21 days depending on the dose injected. Changes in chondrocyte morphology are observed as early as 1 day after MIA injection and loss of chondrocytes starting at day 7. MIA injection also resulted in subchondral bone remodeling 5 to 7 days after injection, evolving into bone sclerosis.³⁵ The eburnation of subchondral bone is usually found at day 28. Synovial membrane hyperplasia and fibrosis are also seen, but only with the high doses. The highest doses of MIA (up to 3 mg per knee in rats) led to total loss of cartilage in 15 days.³⁶ This model also induced osteophyte formation. The inflammatory early phase in this model also features joint swelling and immune cell infiltration of the patellar fat pad, and resolves fully by day 7.

The hyperalgesia induced by MIA injection makes this model attractive for studying OA pain. Data showed the existence of two phases of pain following MIA injection. The first manifests within a day, lasts up to a week after the injection, and appears mediated primarily by inflammation. The second manifests later and is thought to be the result of joint destruction. Hence, in parallel with the degenerative changes, a pain phenotype rapidly develops in the hind limb ipsilateral to the injected knee, suggesting the presence of central sensitization. It was recently shown that at later time points, OA pain in this model is associated with a neuropathic component. However, there is considerable variation in the OA pain level and different pathophysiologic sequelae according to the dose used. An MIA dose higher than 1 mg was suggested to be associated with a much greater degree of neuronal injury and/or central sensitization that includes afferents innervating territories outside of the knee joint, and is suggested to be used to investigate clinical OA pain with neuropathic features or descriptors. This is in line with the finding of a recent study using a very high MIA dose (4.8 mg), which showed that the induction of the ongoing pain originating from the site of injury was dependent on afferent fiber activity.³⁷ Obviously, more studies are needed to better understand the mechanisms of pain induced by this model.

Subjective and objective assays to measure the behavioral endpoints have been used in this model. The pain responses are typically measured by assessing mechanical and/or thermal hypersensitivity of a hind paw as well as by applying calibrated pressure and torque to the knee. Other methods include assessment of hind limb weight bearing, primary mechanical hyperalgesia, hind limb grip strength, and sleep disruption. Recently, two weight-bearing tests that evaluate nonreflexive and nonreferred OA-induced nociception, the Knee-Bend and CatWalk tests, were found to be reliable methods for assessing movement-induced nociception in the MIA rat model.^{38,39} The use of electrophysiologic recordings of nerve fibers provides direct insight into the underlying nociceptive processes.

Other attempts have been made to create mouse and rat OA models through intraarticular knee injection of different proteolytic enzymes such as papain, trypsin, hyaluronidase and collagenase. Convincing results were obtained with the collagenase injection, which induced not only cartilage damage but also joint instability, synovial membrane inflammation, subchondral bone remodeling, and osteophyte formation.⁴⁰ This model was also demonstrated to be associated with an excess production of prostaglandin E₂, an important feature of human OA. However, no correlation was found between the amount of collagenase injected and the level of cartilage damage.

Surgical procedures

A significant number of models have been developed using different surgical procedures. The most common are those induced by joint instability, including ACLT with or without partial or complete ablation of the meniscus, or by artificial induction of metabolic and/or hormonal changes.

Meniscectomy and/or anterior cruciate ligament transection

OA can be surgically induced by meniscectomy or ACLT in guinea pigs and in rats. Models have also been developed in mice that use different combinations of meniscectomy and ligament transection.^{41,42} The latter produced various degrees of OA severity depending on the extent of joint instability. Another model, produced by a surgical tear in the medial meniscus in rats, was demonstrated to induce consistent and reproducible lesions mimicking many of the human OA features.⁴³ In these models, the surgery is most frequently carried out on the medial side of the joint.

These models generally offer the advantage of faster development of OA lesions than in large and medium-sized animals, and structural changes including cartilage lesions and osteophyte formation have been documented up to 12 weeks after surgery. The interventions induce cartilage changes that are typical of OA: histologic changes in cartilage and depletion of cartilage matrix components, which can progress to a total loss of articular cartilage. Moreover, in the rat ACLT model, the early lesions are also characterized by subchondral bone resorption followed by increased formation of this tissue, which is associated with the development of osteophytes in the periarticular zones.⁴⁴

Pain behaviors have been examined extensively in some of the murine surgically induced OA models. Pain assessments included weight bearing, mechanical hyperalgesia, cold allodynia, mechanical allodynia, and vocalization in response to knee compression. Recently developed tools to assess rodent gait characteristics, including spatiotemporal evaluations of gait patterns and dynamic assessments of reaction forces, have been found to be useful.

Weight-bearing assessment of male C57BL/6 mice following destabilization of the medial meniscus (DMM) showed that the pain was biphasic: early pain due to surgery and, from week 12 onward, significant OA pain.⁴⁵ Another study using this model in male and female DC-1 mice demonstrated tactile allodynia in the ipsilateral hind paws starting at 2 and 4 weeks after surgery, respectively.⁴⁶ Assessment of pain by measurement of hind paw weight distribution in rats subjected to medial meniscal tear revealed changes in weight distribution that appeared as early as 3 days after surgery and remained consistent for at least 3 weeks after surgery.⁴⁷ An earlier study reported alterations in weight bearing at later time points following surgery. The difference between these studies was suggested to be due to the procedures and/or rat strains. Although tactile allodynia was observed in only a proportion of the animals,⁴⁷ this subset of animals had histologic changes similar to those in animals that did not exhibit tactile allodynia, which reveals a lack of correlation between pain assessment and joint damage. Moreover, there were no differences in thermal or mechanical hyperalgesia between the two groups.

Studies in the rat ACLT model reported increased paw elevation time for up to 14 days after surgery.⁴⁸ In the rat model combining ACLT and resection of the medial menisci, decreased walking duration on a treadmill was found to be associated with an increase in the number of neurons positive for calcitonin gene-related peptide in the dorsal root ganglion innervating the joint.⁴⁹ In addition to altered sensory function, this model also showed a late onset of electrophysiologic changes, with a pattern consistent with peripheral neuropathy but not peripheral inflammation.⁵⁰

Ovariectomy

Another surgically induced OA model is ovariectomy in the Sprague-Dawley rat. The hypothesis supporting this model is that estrogen deficiency in postmenopausal women is thought to be a risk factor for disease progression. The model is "postmenopausal-like" induced by estrogen deficiency⁵¹ and is characterized by mild erosion of knee cartilage starting at 9 weeks after surgery. This model is influenced by the age of the animal at the time of surgery; rats 5 to 7 months old should be used. Moreover, the joint lesions are compartment specific, with lesions preferentially in the femur. The cartilage lesions are similar to those seen in the early stages of OA in other models, with changes in cellularity and loss of cartilage matrix integrity, including alterations in collagen fibers and structure. Subchondral bone resorption is also observed and is thought to contribute to the disease process. At present, OA pain has not been studied in this model.

Spontaneous osteoarthritis models

Mouse

It is well known that OA can occur naturally in a number of mouse strains, such as the STR/ort, BALB/c, DBA/1, and C57BL/6 mice. These models show many of the features of human OA, including the occurrence of joint space narrowing, cartilage lesions, alterations in cartilage matrix molecules, and osteophyte formation. In contrast to humans, in which OA is more prevalent in females, in STR/ort and DBA/1 mice a higher prevalence is found in males. Although it is well known that the development of OA structural changes is age related, these models have helped to identify other factors that influence disease development. For example, they have revealed the effects of loss of innervation and anatomic abnormalities, as well as the roles played by many important catabolic factors, cytokines, and proteases and, importantly, the role of genetics.

Guinea pig

Spontaneous OA changes have also been shown in Hartley guinea pigs⁵² and develop preferentially in the medial compartment. As is the case with some mouse strains, the male guinea pig is more prone to the development of rapidly progressive OA. Changes can be seen as early as 3 months of age, with lesions of mild to moderate severity found on the medial tibias of most of the animals by 6 months, and severe lesions in the medial compartment at 1 year. The morphologic changes include cartilage fibrillation, subchondral bone remodeling, synovial membrane hyperplasia, and osteophyte formation as well as an increase in collagen turnover and proteoglycan loss.

Recent studies using this model of spontaneous OA have yielded interesting findings. Inhibition of cathepsin K was associated with a reduction in levels of cross-linked C-telopeptides of type II collagen and joint pain.⁵³ Long-term oral administration of glucosamine and chondroitin sulfate inhibited OA progression by downregulating MMP-3 expression.⁵⁴ The importance of an ω -3 polyunsaturated fatty acid diet in maintaining cartilage integrity is supported by a study in which such a diet reduced spontaneous OA in Hartley guinea pigs in association with a decrease in OA disease markers.⁵⁵

Very few studies of OA pain have been conducted using this model. However, one study in which joint nociception was evaluated using electrophysiologic recordings from knee joint afferents revealed increased spontaneous activity and noxious movement-evoked nerve firing in aged animals.⁵⁶

Genetic models

Genetically modified mice are valuable tools for studying the roles of different molecular processes and key mediators involved in the pathophysiology of OA. Genetic modification can consist of gene shutdown by mutation or deletion or of gene overexpression. Some of the genetic modifications have been particularly useful in identification of the roles played by the matrix components in the development of OA cartilage changes and can serve as useful tools for understanding the complex pathophysiology of the disease. For example, collagen type II (COL2A1)-deficient transgenic mice exhibit degeneration of articular cartilage that resembles OA. Knock-out mice lacking α_1 integrin exhibit an aging-dependent OA phenotype. Mice overexpressing MMP-13 in articular cartilage display OA-like characteristics, and tissue inhibitor of metalloproteinase-3 (TIMP-3)-deficient mice exhibit increased aggrecan loss associated with a mild degree of cartilage degradation. Transforming growth factor- β -deficient mice exhibit an OA-like phenotype. Targeted disruption of Mig-6 leads to early-onset degenerative joint disease.

The combination of genetic modification with surgical induction of OA has been especially useful for delineating the *in vivo* roles of a variety of genes involved in cartilage biology and the pathophysiology of OA. Notably, the DMM model in mice has been very informative. For example, the aggrecanases ADAMTS4 and ADAMTS5 have drawn considerable interest as potential therapeutic targets for the treatment of OA. ADAMTS5-deficient but not ADAMTS4-deficient mice subjected to DMM-induced OA showed a protection against cartilage erosion, the occurrence of OA, and subchondral bone changes.^{41,57,58} However, such a finding is in contrast to the results of studies using human chondrocytes and cartilage explants, in which both ADAMTS4 and ADAMTS5 were shown to be involved in the depletion of aggrecan. In addition, when the DMM model was used in mice deficient in syndecan-4 (a member of the transmembrane heparin sulfate proteoglycans), regulation of ADAMTS5 activation and cartilage breakdown during OA was shown to occur via direct interaction with the protease and regulation of MAPK-dependent synthesis of MMP-3.⁵⁹ A recent study in which the receptor EphB4 (a specific receptor of ephrin-B2) was conditionally overexpressed in bone and the mice subjected to DMM surgery identified a

protective role in OA joint tissues.⁶⁰ In another study using the DMM model, TIMP-2-deficient mice developed accelerated OA via promotion of angiogenesis, which suggests that TIMP-2 is essential for maintenance of normal articular cartilage homeostasis.⁶¹

Small animal model limitations

Small animal models are particularly helpful for exploring very specific pathways involved in the pathophysiology of OA and for testing specific DMOAD strategies. They offer several advantages, including low cost and ability to perform a wide variety of studies. However, to date, there have been a limited number of studies in small animal OA models from which results have successfully been extrapolated directly to humans. This being said, the variety of OA models available in small animals presents many opportunities to study the wide range of disease features and also offers the great advantage of rapid disease development compared with the human disease. These models also provide the opportunity to study structural changes in the different joint tissues at the same time. Genetically modified models can be used to validate specific therapeutic targets. Small animal models also allow the comparison of results obtained from spontaneous versus induced OA models to study key phenomena of OA development. In addition, the emergence of tissue-specific genetic modification in mice, such as Cre-lox technology, has enabled the generation of tissue-specific gene-deficient and overexpressing mice, which can facilitate the understanding of the *in vivo* role of each targeted gene in OA pathobiology. These models can also be used to identify the interdependence of the separate joint tissues.

Although they are useful tools for research, it is important to understand the limitations imposed by small animal models. For instance, the sample material available from the articulation and, more precisely, from each tissue, is very limited. Moreover, differences exist among certain models in the severity of structural changes based on gender and body weight, as in the spontaneous OA guinea pig model, as well as in the degree of joint stability. There are some particularities of certain species that must be kept in mind. For example, mice do not express or produce MMP-1, and ADAMTS5 was shown to be of pivotal importance in this model, whereas in humans this is not clear. It was also recently shown that the deleterious effect of activation of the Wnt/ β -catenin pathway in OA cartilage that is seen in small animal models should be revisited because the data indicate that in humans this system inhibits the IL-1 β activation of some MMPs as part of a negative feedback loop counteracting nuclear factor- κ B.⁶² Additionally, the finding that the surgically induced OA rat model better approximates the human condition than the spontaneous OA guinea pig model highlights the need for experimentation in multiple animal models. Although rodent behaviors can be used to describe some of the symptomatic consequences (pain) of OA and behavioral assays have been developed, certain tests may not be

adequate because they rely on stimuli that are not applied to the affected joint; they thus evaluate referred nociception and/or fail to evaluate movement-related nociception, the latter of which is a hallmark of OA-induced pain. With regard to the MIA model, the divergent sequelae following different doses of MIA must be taken into account, especially when indirect outcome measures of joint pain have been employed and when higher doses are used.

CONCLUSION

Animal models of OA have been shown quite convincingly to be useful in the study of the evolution of joint structural changes that occur during OA and in the exploration of the different pathophysiologic mechanisms responsible for those changes. Obviously, there are a number of limitations of OA models. For instance, the advantages of spontaneous versus induced OA models and large versus small animal models are still under debate, and the mechanisms leading to the structural changes observed in spontaneous OA models remain largely unknown. Each offers advantages and disadvantages. Spontaneous OA models are useful in the study of the primary onset of OA and can be applied to investigate prevention and treatment. However, use of these models can be time-consuming, and differences exist in the onset, incidence, and severity of the disease among animal species. Surgically induced OA models develop damage rapidly and reproducibly. Nonetheless, they are mainly posttraumatic models, and the disease at first involves biomechanical instability. Intraarticular administration of agents generates OA in a short time, and these models can mimic the final stage of OA, at least in cartilage. These models are valuable mainly for investigating pathologic processes in cartilage and the therapeutic effects of drugs in this tissue. This could be a concern because, although articular cartilage degradation was once considered the hallmark of OA, the concept of the joint as an organ is now recognized as fundamental to basic and clinical research in OA, and at present the theory put forward is that a DMOAD has to modulate more than one tissue of the joint to be effective. Genetically modified mice are used for mechanistic studies aimed at understanding the functional role of specific molecules in OA pathologic processes. Reservations include their frequent lack of physiologic relevance to the human disease and their use as drug-screening tools; in addition, these studies are time-consuming and expensive.

Acknowledgments

Pathogenesis and pathology of osteoarthritis

■ THOMAS AIGNER ■ NICOLE SCHMITZ ■ DONALD M. SALTER

- Osteoarthritis (OA) is characterized primarily by focal cartilage damage, bone sclerosis, and synovioathy.
- Changes within the articular cartilage can be categorized by typing, staging, and grading of the lesions.
- OA is strongly associated with age, but bone and cartilage changes in OA are different from those of normal aging.
- There are many different hypotheses that try to explain cartilage and joint degeneration, including chronic mechanical (over)load, matrix proteolysis, age-induced changes in the cartilage matrix and the chondrocytes, and increasing damage to the genomic DNA of the chondrocytes leading to a deranged cellular phenotype.
- The production of proinflammatory cytokines as well as the activation of cellular inflammatory signaling pathways, including interleukin-1 and the MAP kinases, likely play an important role in OA pathogenesis.
- Biomechanical factors are essential in the pathogenesis of OA. Altered joint biomechanics are generated by joint incongruity, laxity, muscle weakness, and impaired proprioception in addition to trauma and heavy physical load.
- Despite the fact that presumably a great variety of different phenomena contribute to the pathogenesis of OA, premature aging of the chondrocytes and the matrix probably plays a crucial role in its initiation and progression; thus OA might be in analogy the “morbus Alzheimer” of the joint.

INTRODUCTION

Osteoarthritis (OA) is the most common form of arthritis and the leading source of physical disability with severely impaired quality of life in people in industrialized nations. Although derived from the Greek words *osteon* for bone, *arthron* for joint, and the suffix *-itis* for inflammation, the site of the most pronounced structural alterations is not the bone but the joint cartilage, and severe inflammation is seen in only a few patients. OA is generally considered a disease of the elderly, progressively causing loss of joint function, but although it is true that OA prevalence increases sharply with age it is not part of normal aging. Very little is known about the underlying causes of OA, and many hypotheses regarding its pathogenesis have been proposed. Genetic defects causing malfunction of structural genes give rise to premature and often severe OA in certain families, but in the majority of OA cases no such defects have been identified. Risk factors other than age include obesity, metabolic diseases, joint malalignment, and joint trauma. Each can contribute to the initiation and progression of the disease in different compartments of the joint. Biochemical processes involving cartilage, bone, and synovium eventually intertwine and collectively damage all three joint compartments. This results in articular cartilage breakdown, osteophyte formation, subchondral bone sclerosis, bone marrow lesions, and changes in the synovium that manifest as episodic synovitis (Fig. 175.1). Advances in molecular biology raise hopes that new therapeutic targets will be identified that will allow more than just symptomatic therapy. Joint replacement is still the unsurpassed therapy for advanced and incapacitating OA. However, with increasing appreciation of the contribution of all three joint compartments to disease progression, research in OA pathogenesis, biomarkers, and treatment has broadened immensely, and many new potential therapeutic targets have emerged over the past years.

THE NORMAL JOINT: ANATOMY, PHYSIOLOGY, AND FUNCTION

Understanding joint dysfunction requires some knowledge of the normal joint and comparison of the diseased state with the physiologic situation (Fig. 175.2). The most important requirements for normal joint function are the freedom of the opposed articular surfaces to move pain free and largely friction free within the required range of motion as well as to distribute load correctly across joint tissues. Thus a pathologic condition in many cases might be caused by acute or chronic mechanical overloading, systematic mal-loading, or habitual underloading leading to disuse atrophy.

Correct functioning of the joint is largely dependent on its design. Joints are highly specialized organs whose properties are provided by the articular cartilage, which, under physiologic conditions, is capable of sustaining high cyclic loading. Articular cartilage covers the joint surfaces and is mainly responsible for the unique biomechanical properties of the joints. Joints are complex composites of different types of connective tissue, including subchondral bone, cartilage surfaces, ligaments, and the joint capsule. The bone defines the shape of the joint, and the articulating surfaces—in combination with the articular cartilage—determine the absorption properties during movement. The synovial capsule and, in particular, the synovial membrane (i.e., the synovial lining cell layer) also contribute to the physiologic functioning of the articulating joints. The synovial capsule, together with the ligaments, provides the mechanical stability of joints and ultimately determines their flexibility and range of motion. The synovial membrane, containing highly metabolically active surface cells, or synoviocytes, plays a crucial role in nourishing the chondrocytes as well as maintaining the normal metabolic milieu within the joint by removing metabolites and matrix degradation products from the synovial space. Synoviocytes also produce large amounts of important mediators (cytokines and growth factors), matrix-degrading enzymes, as well as hyaluronic acid and other factors such as lubricin/superficial zone protein that aid joint lubrication and free movement. For this reason, all tissues and cells within the joint act to maintain the local milieu of the synovioarticular joint organ and work in concert to allow optimal function and integrity of joints.

PATHOLOGY

The progressive macroscopic and histologic changes in articular cartilage in OA are well recognized (Figs. 175.3 and 175.4). Macroscopically, normal hyaline articular cartilage is smooth and pale cream to yellowish in color. In OA the cartilage appears more discolored, soft, and roughened with the underlying subchondral bone exposed in later stages (see Fig. 175.3f and g). These changes can be seen and graded radiographically (see Chapter 177) and can be visualized in more detail histologically (see Fig. 175.4). In early OA cartilage volume is increased due to increased water content and proteoglycan swelling, which occurs secondary to physical or proteolytic disruption of the type II collagen network. Subsequently, cartilage proteoglycan content decreases, a result of increased expression and activity of matrix-degrading enzymes (see Fig. 175.4b). As OA progresses direct physical forces on the weakened cartilage cause surface matrix fibrillations, cracks in the superficial layer of the articular cartilage that run parallel to the surface. These cracks extend, following the tangential and vertical orientation of the collagen fibers in the mid and deep cartilage zones. Fissures branch and propagate as a result of ongoing mechanical trauma, and this, in conjunction with continuing proteolytic activity, leads to progressive cartilage loss (see Fig. 175.4e). In contrast to the reduction in the volume of noncalcified articular cartilage, the thickness of the calcified cartilage zone increases and is associated with duplication/multiplication

Fig. 175.1 In osteoarthritis (OA) the articular cartilage is lost or severely thinned, the (subchondral) bone is sclerotic, the joint capsule is thickened, and the synovial membrane is activated. (Courtesy E. Bartnik, Frankfurt.)

and vascular invasion and innervation through the tidemark that separates calcified from noncalcified cartilage. Microcracks also appear in the calcified cartilage and may initiate bone remodeling. The duplication/multiplication of the tidemark reflects episodes of tidemark advance, which also contribute to cartilage thinning. The subchondral bone becomes thickened, giving rise to radiologic subchondral sclerosis, and areas of failed efforts to repair subchondral bone fractures develop into radiolucent cysts containing myxoid and fibrocartilaginous tissue. Osteophytes arise at the periphery of the joint from perichondral/periosteal stem cells that are induced to proliferate and undergo chondrogenic differentiation under the influence of growth factors such as transforming growth factor- β (TGF- β). A similar but less structured process is observed in the areas of the eburnated bone, in which the articular cartilage is absent. Here, metaplastic cartilage in the form of nodules or tufts is found either within the bone marrow or at the naked bone surface.

TYPING, STAGING, AND GRADING OF JOINT CARTILAGE ALTERATIONS IN OSTEOARTHRITIS

The classification of OA cartilage degeneration is complex because patients have a variety of histories, symptoms, and morphologic changes. Common to all, however, are symptoms of pain or limitation in joint movement associated with structural joint (cartilage) damage. Although other joint tissues are involved in OA, cartilage has traditionally been used to score OA severity. In general, the process of joint destruction can be evaluated with regard to the pathogenesis ("typing"), the extent ("staging"), and the degree of the most extensive focal damage ("grading").¹

Fig. 175.2 Coronal magnetic resonance imaging data sets of the knee acquired using a fast low-angle shot (FLASH) or spoiled gradient echo (SPGR) sequence. This imaging sequence has been extensively validated for detecting cartilage lesions and for performing quantitative measures of cartilage volume and thickness. The left image shows a healthy knee with normal cartilage thickness, the right image a knee with osteoarthritis. Note the osteophytes and the extensive cartilage loss in the lateral femorotibial compartment. (Courtesy Felix Eckstein, Salzburg, Austria.)

Fig. 175.3 (a) Macroscopic appearance of the femoral condyles of a normal knee. (b) Femoral condyles of a severely damaged knee. (c) Arthroscopic image of a cartilage defect of the femoral condyle within the knee joint. (c, Courtesy Dr. W. Eger, Rummelsberg, Germany.)

Fig. 175.4 Conventional histologic preparations show fibrillation and matrix loss in osteoarthritic (OA) cartilage (b) compared with normal cartilage (a). In severely damaged areas nearly all articular cartilage is destroyed (e). Also a moderate (d) to severe (e) loss of proteoglycans is found, as visualized by toluidine blue staining. Besides changes in articular cartilage, changes in the subchondral bone are prominent in OA as well; namely, thickening of the subchondral bone plate (f) compared with normal (c).

BOX 175.1 TYPING OF JOINT DESTRUCTION

Primary

No (major) causative reason known

Secondary

- Articular gout
- Bone infarction
- Endocrine disorders (e.g., hyperparathyroidism, hypothyroidism)
- Hemophilia
- Intraarticular infections
- Joint instability (e.g., ligament and meniscus lesions)
- Neuropathic arthritis (e.g., Charcot joint)
- Overload causing excessive wear (work, sports, varus or valgus deformity)
- Paget disease
- Trauma

Typing relates mostly to classification as primary (idiopathic) OA or secondary OA (caused by another disorder). Primary OA is most frequently observed. Although the designation “primary” implies that there is no obvious cause, minor preexisting conditions (i.e., preconditions or risk factors) still may exist in this type of OA. The major causes leading to secondary OA are listed in [Box 175.1](#).

Grading and staging are more debated. *Grading* should refer to evaluation of histologic changes at one (arguably the worst) site of joint destruction, whereas *staging* should refer to assessment of how far the overall disease has progressed toward an end stage (in analogy to grading and staging of tumors). Both represent an attempt to score processes relevant to the disease.

The grading system most commonly used (partly with minor modifications) is the histochemical-histologic grading system of Mankin and coworkers ([Table 175.1](#); [Fig. 175.5](#)).² Criticisms of the Mankin system

TABLE 175.1

Grading of osteoarthritis according to Mankin and colleagues (1971)

Feature	Score	Histologic feature
Cartilage structure	0	Normal
	1	Superficial fibrillation
	2	Pannus and superficial fibrillation*
	3	Fissures to the middle zone
	4	Fissures to the deep zone
Chondrocytes	5	Fissures to the calcified zone
	0	Normal
	1	Diffuse hypercellularity
	2	Cell clusters
	3	Hypocellularity
Safranin O staining	0	Normal
	1	Slight reduction
	2	Moderate reduction
	3	Severe reduction
	4	No staining
Tidemark	5	Total disorganization*
	0	Intact
	1	Tidemark penetrated by vessels†

*Might best be removed (relates to osteophyte formation).

†Might best be supplemented with “or duplicated tidemark.”

TABLE 175.2

Grading scheme originally suggested by Outerbridge (1961) for macroscopic changes seen on the patella

Grade I	Softening and swelling of the cartilage
Grade II	Fragmentation and fissuring in an area ≤ 0.5 inch in diameter
Grade III	Area more than half an inch in diameter is involved
Grade IV	Erosion of cartilage down to bone

From Outerbridge RE. The etiology of chondromalacia patellae. J Bone Joint Surg Br 1961;43:752-7.

include the fact that there can be high interindividual variability that might be related to the experience of the users. Additionally some of the subcategories of the Mankin score do not assess primary cartilage degeneration but describe features observed in secondary cartilage formation (e.g., osteophyte formation) and should be excluded in future scoring attempts. Whereas the Mankin system addresses the part of the joint cartilage that is viewed under the microscope, scoring systems that look at the whole joint surface macroscopically—but also, if needed, the worst lesion histologically—provide additional information. The Outerbridge system (Table 175.2) was described primarily for the patella but later was successfully applied to other joints. At the site of the greatest cartilage damage, grading and staging are closely correlated. A purely macroscopic staging system is too imprecise for scientific purposes, and a new scoring system has been proposed by Pritzker and colleagues³ (Table 175.3) that combines histopathologic grading parameters with the extent of the lesions. With new scientific insights and more extensive and specific medical therapeutic options it is likely that more elaborate and validated grading and scoring systems will need to be developed. Of crucial importance will be the use of defined and unified nomenclature to make studies, descriptions, and results comparable. Currently, similar-sounding terms are used for partly different phenomena and different-sounding words are used for the same entity (e.g., fissuring, clefting, flaking). Therefore a consensus nomenclature has been proposed by the Osteoarthritis Research Society International (OARSI)⁴ (Table 175.4).

TYPING AND GRADING OF SYNOVIAL MEMBRANE ALTERATIONS IN OSTEOARTHRITIS

Clinically relevant OA is invariably associated with some sort of pathologic synovial changes. This reflects the notion of a direct relation between clinical symptoms and the synovial reaction in OA. Most likely these changes

TABLE 175.3

Scoring of osteoarthritis according to Pritzker and colleagues (2006)

Grade	Histologic properties
0	Matrix: surface intact (normal architecture) Cells: intact, appropriate orientation
1	Matrix: superficial zone intact, edema and/or superficial fibrillation (abrasion), focal superficial matrix condensation Cells: cell death, proliferation (cluster formation), hypertrophy
2	As above: Matrix: discontinuity at superficial zone (deep fibrillation) ± Loss of proteoglycan staining in upper third of cartilage ± Focal perichondral increased proteoglycan staining in middle zone ± Disorientation of chondron columns
3	As above: Matrix: vertical fissures into middle zone and branched fissures ± Loss of proteoglycan staining into lower two thirds of cartilage ± New collagen formation cells: cell death, regeneration, hypertrophy in cartilage domains adjacent to fissures
4	As above: Cartilage matrix loss with delamination of superficial zone Excavation with matrix loss from superficial to middle zone ± Formation of cysts in the middle layer
5	Complete matrix loss with denudation of the sclerotic subchondral bone or fibrocartilage ± Microfracture with repair limited to bone surface
6	Bone remodeling (more than osteophyte formation only) with microfracture, fibrocartilage, and osseous repair above the previous surface

Data from Pritzker KP, Gay S, Jimenez SA, et al. Osteoarthritis cartilage histopathology: grading and staging. Osteoarthritis Cartilage 2006;14:13-29.

are at least partly involved in the progression of the disease. In OA four different types of OA synoviopathies are identified: hyperplastic, inflammatory, fibrotic, and detritus rich (Table 175.5).⁵

Detritus-rich synovitis, which is found in end-stage OA disease, is due to abundant macromolecular cartilage and bone detritus (i.e., bone and cartilage fragments attached to or incorporated into the synovial membrane; Fig. 175.6h and i) in addition to molecular debris that is not visible microscopically. A significant amount of fibrinous exudate is also found at the synovial membrane surface. This exudate may be combined with incorporated fibrin, which reflects longer ongoing fibrinous exudation being

■ TABLE 175.4

OARSI terminology for osteoarthritic joint pathology—a proposal for a consensus

Preferred term	Definition	Synonym
Superficial zone	Includes the surface and upper zones.	
Surface zone	Cartilage zone immediately subjacent to the joint surface. Collagen fibers are aligned parallel to surface (without cells). This zone might be not be present in normal cartilage samples or in some species.	Lamina splendens
Upper zone	Collagen fibers are aligned parallel to surface. Chondrocytes, elongated and flattened, are aligned parallel to collagen fibers and to joint surface.	Horizontal zone/layer Tangential zone/layer Superficial zone/layer
Middle zone	Zone subjacent to upper zone. Collagen fibers are aligned intermediately between upper and deep zone alignments. Chondrocytes are in groups (chondrons) aligned parallel to collagen fibers.	Transitional zone/layer Intermediate zone/layer
Deep zone	Zone subjacent to middle zone and above calcified cartilage.	Radial zone/layer
Upper deep	Collagen fibers are aligned predominantly perpendicular to joint surface.	
Lower deep	Chondrocytes within chondrons are aligned parallel to collagen fibers and perpendicular to joint surface.	
Tidemark	Zone of increased calcification at border of uncalcified and calcified cartilage.	Calcification front
Penetration		Ligne bordant (increased basophilic stain)
Advancement		
Duplication/multiplication		
Calcified cartilage	Zone between tidemark and subarticular bone plate.	Calcified zone
Surface undulations	Surface irregularities that do not involve discontinuity of the articular surface.	Roughening Unevenness
Fissure	Vertical cracks, irregularities, or discontinuities of cartilage matrix.	Cleft Crack
Superficial	Restricted to surface and superficial zone.	Flaking Fraying
Middle	Restricted down to middle zone.	Fibrillation
Deep	Restricted down to deep zone.	Fissuring
Simple	Unbranched fissure.	
Complex	Branched fissure.	
Split/splitting	Horizontal (0 to 60 degrees to cartilage surface) matrix cleft/separation.	
Erosion	Loss of articular cartilage tissue including superficial and at least portions of deeper cartilage layers.	Loss
Surface		Ulceration
Into the superficial zone		Abrasion
Into the middle zone		Delamination
Into the deep zone		Flaking
Full depth		Spallation Excavation
Eburnation	Smooth shiny bone surface indicative of exposed bone at articular surface.	Denudation

■ TABLE 175.5

Major histopathologic features of the four patterns of osteoarthritis-associated synoviopathy in comparison to each other and to normal synovial membrane

	Normal	Hyperplastic synoviopathy	Inflammatory synoviopathy	Fibrotic synoviopathy	Detritus-rich synoviopathy
Villous hyperplasia	—	++(+)	++(+)	++(+)	++(+)
Synovial lining—proliferation	—	+	++	++	++(+)
Synovial lining—activation	—	+	++	+	+
Fibrinous exudate	—	—	(+)	+	++(+)
Capsular fibrosis	—	—	(+)	+++	+++
(Macromolecular) cartilage and bone debris	—	—	(+)	—	+++
Granulocytic infiltrate	—	—	—	—	+
Lymphoplasmocellular infiltrate—diffuse	—	—	++	(+)	++(+)
Lymphoplasmocellular infiltrate—aggregates/follicles	—	—	++	(+)	(+)

From Oehler S, Neureiter D, Meyer-Scholten C, et al. Subtyping of osteoarthritic synoviopathy. *Clin Exp Rheumatol* 2002;20:633-40.

Fig. 175.6 Normal synovial membrane (a and b) shows a rather flat surface with a flat layer of inactive, nonproliferated layer of synoviocytes. In contrast, in osteoarthritis (OA), at least in some cases, synoviocytes are severely activated and proliferated (c) similar to the situation found in rheumatoid arthritis. In late-stage OA most synovial specimens show a moderate to abundant synovial hyperplasia (d and e) and often some sort of capsule thickening (e). In a minority of cases OA synovial membranes show mild to moderate inflammatory infiltrates (f and g) usually lying in aggregates around blood vessels (f). In some cases lymphoid follicles also are found (g). End-stage rapid progressive cartilage destruction leads to detritus-rich synovitis with cartilage and bone fragments incorporated into fibrinous exudate (i, van Gieson stain) or the synovial stroma (h). (Reprinted with permission from Aigner T, van der Kraan P, van den Berg W. Osteoarthritis and inflammation— inflammatory changes in osteoarthritic synoviopathy. In: Buckwalter JA, Lotz M, Stoltz JF, editors. *Osteoarthritis, inflammation and degradation: a continuum*. Amsterdam: IOS Press; 2007, p. 219-30.)

organized. Detritus-rich synovioarthritic lesions usually contain a minor inflammatory cell infiltrate consisting of lymphocytes and granulocytes as well as some foreign body giant cells. Another form of OA synoviopathy found in late-stage disease, fibrotic OA synoviopathy (capsular fibrosis) (see Fig. 175.6e),⁵ is characterized mainly by shortening and thickening of the joint capsule. This may be partly responsible for some symptoms such as joint stiffness in OA patients.

The most interesting of the OA synoviopathies, in terms of pathogenesis, is inflammatory OA synoviopathy, which is characterized by moderately

extensive lymphocytic infiltrates (see Fig. 175.6f and g). It is intriguing to speculate whether this condition reflects an autoimmune process that may be occurring, at least in this subset of OA patients. The lymphocytic infiltrate in the subsynovial stroma appears to correlate directly with interleukin-1 β (IL-1 β) in the synovial fluid as well as matrix metalloproteinase-1 expression by synoviocytes, which suggests a direct stimulatory role of the inflammatory cells on the activity of the synovial lining cells. The presence of inflammation in a significant portion of OA patients points to the option of antiinflammatory therapy for some subsets of OA patients.

In early OA, a mostly hyperplastic OA synoviopathy is found (see Fig. 175.6d). This pattern shows only moderate synovial hyperplasia, with or without cellular activation but without significant capsular fibrosis or significant inflammatory cell infiltration or detritus. Overall, three forms of alterations to the synovial surface are seen:

1. Cytoplasmic volume of the usually flat synovial lining cells (hyper-trophy) increases. These cells may become cuboidal or even cylindrical, which suggests that they have been activated in some way (see Fig. 175.6c).
2. The normal single (flat) cell layer of synovial lining cells (see Fig. 175.6a and b) proliferates to form as many as five cell layers (hyperplasia)
3. The whole synovial surface, including the underlying stroma, can become hyperplastic and form the classic synovial villi.

Synovial hyperplasia per se can be found in all forms of OA synoviopathy and in chronic synovitis. Thus villous hyperplasia is largely a nonspecific feature of chronic synovial alteration and activation.

A well-established scoring system is not yet available for human OA synoviopathy. A simple scoring system proposed by Krenn and colleagues⁶ to separate inflammatory and noninflammatory synovial alterations is based mainly on the intensity of inflammatory infiltrates and synovial and stromal activation. In 2002 a scoring system specifically for OA synoviopathy was developed that divided the OA-associated synoviopathies into the four categories noted earlier (see Table 175.5)—hyperplastic, fibrotic, inflammatory, and detritus rich—which are subdividable into mild, moderate, and strong

depending on the intensity of changes present.⁵ This system aims to reflect the different roles of OA synoviopathy and their implications for the clinical disease. Regardless of the scoring system used, it is important that changes present in the overall joint be averaged because synovial changes are notoriously heterogeneous within affected joints and a single assessment may give erroneous results.

EVALUATION OF REGENERATIVE CARTILAGE FORMATION IN OSTEOARTHRITIC JOINTS (CHONDRO-OSTEOPHYTE FORMATION)

Central for a basic understanding of osteophytic tissue is an analysis of the developmental steps during osteophyte formation. Although it is clear that osteophyte development is a continuous process and many osteophytes show various portions in different stages at the same time, basic steps can be defined based on the cellular phenotype and the matrix composition of the predominating tissue (Fig. 175.7).⁷ To date, the molecular mechanisms in the development of osteophytes are largely unknown. Mechanical or biochemical stimuli could play a central role. However, most osteophytes do not take part in the articulating process and are subsequently not exposed to major mechanical load. Thus it is more likely that growth factors play a dominant role in the induction and promotion of osteophyte formation. For example, the exogenous application of TGF- β and bone morphogenetic protein type 2 into knee joints of adult mice leads to significant osteophyte formation.

Fig. 175.7 Osteophyte development can be subdivided into four stages with different structural organization, although at a given time many osteophytes show different areas that are at different stages. Stage I (early chondrocytes) is characterized by the first chondrocytic differentiation of previously undifferentiated mesenchymal precursor cells (b, g, k). In stage II (chondrocytes) there are extensive areas of newly formed cartilage, but no (endochondral) bone formation is observed (c, h, k). Stage III (early osteophytes) is characterized by an arrangement similar to that of the fetal growth plate cartilage with hyperplastic differentiation in the deepest cartilage layers and active bone formation underneath (d, i, k). In stage IV (mature osteophytes) a structure most resembling hyaline articular cartilage physiologically covers the joint surfaces (e, j, k). Normal periosteum is shown in a and f (a to e, hematoxylin-eosin; f to j, toluidine blue). Col, collagen; GAGs, glycosaminoglycans. (Reprinted with permission from Gelse K, Söder S, Eger W, et al. Osteophyte development—molecular characterization of differentiation stages. *Osteoarthritis Cartilage* 2003;11:141-8.)

Fig. 175.8 Articular cartilage consists mainly of extracellular matrix (more than 95% of tissue volume), its functional element. Interspersed in between the abundant matrix are the cells, the chondrocytes, which are the living (i.e., reacting) element of the articular cartilage tissue. (Reprinted with permission from Aigner T, Sachse A, Gebhard PM, et al. *Osteoarthritis: pathobiology—targets and ways for therapeutic intervention. Adv Drug Deliv Rev* 2006;58:128-49.)

Osteophytes could be considered as attempts at endogenous repair in degenerating joints; an increase in the articulating joint surface might represent a response to mechanical overloading and thus have a supportive function. However, osteophytes are found mainly in non-weight-bearing areas, and their mechanical stability and biologic benefit are questionable. Understanding osteophyte formation and classifying its maturation stage is interesting in itself to understand changes going on in the chondro-osseous department in OA joints, but in addition osteophyte formation represents an interesting *in-vivo* model system for understanding and evaluating processes occurring after many modern cartilage repair strategies (e.g., transplantation of mesenchymal precursor cells to fill up cartilage defects).

ANIMAL MODELS OF OSTEOARTHRITIS

Animal model systems represent an important adjunct and substitute for studies of OA in humans. They provide means to study OA pathophysiology as well as assist in the development of disease-modifying therapeutic agents and biologic markers for diagnosing and determining a prognosis for the disease. Not surprisingly, identification of an optimal model system for the human disease is difficult or impossible, and a number of models involving various species are currently in use. These include models of spontaneous OA as well as models in which OA is induced (surgically, enzymatically/chemically, mechanically, or genetically) (see Chapter 174). Unfortunately, all the models differ somehow, and no gold standard has yet been identified. Given this heterogeneity of the OA disease process, identification of an appropriate disease mechanism-oriented model may be a more realistic goal and better suited to a particular investigation than the “universal model” that has not yet been identified. Rather, as a consequence of the heterogeneity of this disease in humans, a plethora of models is required.

PATHOGENETIC CONCEPTS IN OSTEOARTHRITIS

OA is a heterogeneous condition, and most likely there are many different causes that initiate or promote the disease process. An overview of the relevant pathogenetic concepts for OA is provided here.

Articular cartilage and the extracellular matrix

Articular cartilage is a highly specialized and uniquely designed biomaterial (see Chapter 5). It is largely an avascular, aneural, and alymphatic matrix that is synthesized by the sparsely distributed resident cells—the chondrocytes. The cartilage matrix can be subdivided into different cartilage zones—superficial, radial, deep, and calcified—based on the arrangement of the cells and the matrix fibrils; it can also be separated into different compartments depending on its relationship to the cells: the pericellular matrix is immediate to the cells, the interterritorial matrix compartment represents the major portion of the cartilage matrix at a distance from the cells, and the territorial matrix is the cell-associated compartment in between, which

has not really been well defined and characterized (Fig. 175.8). In terms of physical properties, tensile strength comes from the collagen network, which hinders expansion of the viscoelastic aggrecan component. The aggrecan-hyaluronan aggregates bind high amounts of water owing to their extensive fixed charges and are responsible for the resistance to compression of the tissue. Thus, under compression, the cartilage matrix is compliant but rapidly regains its elasticity as water molecules are drawn back into the matrix on unloading by the strongly hydrophilic aggrecan aggregates.

Most of the cartilage matrix is formed during fetal development and the phase of skeletal growth until the closure of the growth plates at the end of adolescence. Indeed, the collagen backbone appears to show virtually no turnover during life, at least in the (inter)territorial matrix compartments. However, other matrix components—namely, the large aggregating proteoglycan aggrecan and the small proteoglycans as well as some collagen types (e.g., types VI and IX)—show a significant turnover throughout life. This physiologic turnover is highly relevant for the maintenance of the cartilage matrix integrity on the molecular and particularly the macromolecular level.

Pathologic matrix degradation

One major threat to the cartilage matrix⁸ and thus to the integrity of articular cartilage are matrix-degrading enzymes that destroy the collagen network and proteoglycans (Fig. 175.9). Besides direct degradation of molecular components, destabilization of the supramolecular structures also takes place and plays an important role in the loosening of the overall matrix architecture.

The destruction of articular cartilage and the loss of its biomechanical function is largely due to the destruction and loss of the (inter)territorial cartilage matrix. So far, our knowledge focuses on degradation processes of the two major components of the interterritorial cartilage matrix: the collagen network and the interwoven proteoglycan aggregates. Loss of aggrecan and its fixed negative charges is characteristic of the early stages of cartilage degeneration, whereas the overall content of collagen remains rather constant nearly throughout the disease process. Still, loosening of the collagen network is also a major feature in early cartilage degeneration. As yet it is unknown which is primary—the loss of proteoglycan or loosening of the collagen network—because each eventually influences the other. Loosening of the collagen network leads to a loss of proteoglycans, and a loss of proteoglycans leads to a mechanical overload and thus damage to and loosening of the collagen network. In particular, the latter appears to be responsible for the hyperhydration of articular cartilage in the early phases of the disease process, which is macroscopically visible as softening and swelling. Degradation processes appear to be prominent specifically in the surface zone and around the chondrocytes. Enhanced levels of many metalloproteinases including matrix metalloproteinases (MMPs), as well as members of the ADAM (a disintegrin and metalloproteinase) and ADAMTS (a disintegrin and metalloproteinase with thrombospondin type 1 motif) families are the most likely candidate enzymes responsible for the increased matrix degradation in OA cartilage.⁹ So far it is rather enigmatic which proteases are really crucial for the degradation of the various cartilage matrix components,

THE HALLMARK OF OA CARTILAGE DEGENERATION IS A LOSS OF CARTILAGE MATRIX HOMEOSTASIS

Fig. 175.9 In osteoarthritic (OA) cartilage, the insufficiency of anabolic factors such as insulin-like growth factor 1 (IGF-1) and bone morphogenetic proteins (BMPs) in combination with an increased influence of catabolic factors such as interleukin-1 β (IL-1 β) and tumor necrosis factor- α (TNF- α) result in an overexpression of matrix-degrading proteases (collagenases, aggrecanases, and gelatinases). The catabolic activity of these enzymes cannot be counterbalanced by the concurrent increase in anabolic activity (i.e., expression of aggrecan and collagen types II, VI, and others). ADAMTS, a disintegrin and metalloproteinase with thrombospondin type 1 motif; MMP, matrix metalloproteinase.

although MMP-13 is certainly a top candidate for primary collagen type II fibril degradation, MMP-2 (gelatinase A) is a good candidate for subsequent cleavage of denatured collagen fibrils (gelatins), and ADAMTS-4 and ADAMTS-5 are favored to be the major aggrecanases responsible for the proteoglycan breakdown.

Age-induced degenerative changes in the cartilage matrix

The extracellular matrix changes with age. There is accumulation over time of physically damaged and proteolytically cleaved matrix molecules that are not sufficiently removed and replaced as part of a permanent physiologic turnover of cartilage. These damaged components threaten the functional integrity of the cartilage matrix under physiologic or excess mechanical stress. In addition, molecular modifications of the matrix occur that influence the functional integrity. The collagen network stiffens due to increased covalent, cross-linking of the single collagen chains, which makes the fibrillar network more rigid and less flexible for physiologic deformation occurring during joint loading and movement. In consequence, the collagen network is prone to microfracturing during compression and undergoes molecular disintegration. Aggrecan molecules also change with age. Aggrecan monomers and polymers get smaller and have fewer sugar side chains. Interestingly, not only is this related to accumulating molecular degradation but also newly synthesized aggrecan aggregates appear to be smaller in aged tissue and thus carry lower fixed charges. Although the molecular mechanisms driving this decline are so far unclear, severely reduced sugar side chains significantly limit the ability of aggrecan to bind water and thus to maintain the elasticity of the articular cartilage matrix.

The time-dependent formation of advanced glycation end products is another interesting phenomenon involving posttranslational, nonenzymatic protein and lipid modifications that contribute to changes in matrix biochemistry and chondrocyte biology in aging cartilage. The accumulation of advanced glycation end products has been shown to increase the stiffness of the collagen network and can downregulate the anabolic activity of chondrocytes, further unbalancing cartilage tissue homeostasis.

Crystal deposition disease

Inorganic crystals are not infrequently observed within the articular tissues of degenerate joints. In general three major forms of crystals are seen in synovial joints: monosodium urate crystals (gout; see Chapter 187), basic

calcium phosphate, and calcium pyrophosphate dihydrate (pyrophosphate arthropathy or chondrocalcinosis articularis; see Chapters 190 and 191). Calcium pyrophosphate dihydrate crystals are strongly associated with OA cartilage degeneration and can be detected on routine radiography and by conventional polarizing microscopy. Overall, the cause and relevance of chondrocalcinosis continue to be ambiguous; clearly, it is well correlated with the degeneration of the articular cartilage and it is thought to be related to a metabolic imbalance within the cells and the tissue, most likely the articular cartilage and the chondrocytes. However, so far it remains unclear which comes first—the cell and matrix degradation or the crystal formation. Most likely they promote each other, with metabolic disturbance leading to cellular degeneration and vice versa.¹⁰

Role of biochemical differences

An interesting feature of OA is that not all joints are affected equally. Knee and hip joints are most often involved, whereas ankles are generally spared in symptomatic OA. Although it is obvious that there are anatomic differences between the ankle and knee joint, this alone does not explain why the knee is more susceptible to OA. Studies comparing knee and ankle cartilage have identified several biochemical differences that might be of additional relevance (Table 175.6): (1) differences in biochemical composition and biomechanical properties of the matrix resulting in higher dynamic stiffness of the ankle cartilage, (2) decreased response to catabolic factors such as IL-1, and (3) more efficient matrix repair with an increase in collagen type II synthesis and aggrecan turnover seen in ankle lesions.¹¹ Thus there seem to be differences not only in the anatomy and morphology of the joints and their cartilage but also in the cellular phenotype of the chondrocytes themselves, which may explain why some joints are less prone to develop OA than others.

The articular cartilage and chondrocytes

The articular cartilage consists mostly of extracellular matrix. This matrix is the functional element of the cartilage tissue; that is, the matrix provides the mechanical properties of the cartilage tissue. However, the cells (i.e., the chondrocytes) represent the only vital element of the cartilage tissue, although they represent only about 2 to 3 volume percent of the articular cartilage in the adult. Thus, besides changes in the extracellular matrix, changes within the cells also are obviously potential causes of the OA disease process, and the study of the chondrocyte cell phenotype and behavior (Fig. 175.10) can provide substantial scientific insights into the disease mechanisms of OA.

Developmental history as a model of chondrocyte reactivity in the adult

A very important and interesting aspect of cellular behavior in the adult organism is the recapitulation of molecular mechanisms that occurred during fetal development (Fig. 175.11). This phenomenon is also true for OA chondrocytes. In fact, many of the biologic changes that occur in OA cells mimic a differentiation pattern characteristic of fetal skeletogenesis. This includes changes not only in cellular phenotypes and in anabolic and catabolic events but also in other basic mechanisms such as matrix calcification, apoptosis, and proliferation. Thus these evolutionary and developmental comparisons are attractive for explaining chondrocyte behavior and disease pathways in the adult, but uncoordinated degenerative events should not be mistaken for tightly regulated developmental processes (Fig. 175.12). Both scenarios presumably involve similar molecular and regulatory events, but just as in a jigsaw puzzle, the assembly is the challenge.

The osteoarthritis chondrocyte phenotype

Chondrocytes in normal adult articular cartilage are stable, postmitotic, differentiated cells that maintain tissue homeostasis by synthesizing very low levels of extracellular matrix components to replace damaged molecules, thus preserving the structural integrity of the cartilage matrix. The cells are the major regulators of the matrix anabolism and catabolism of articular cartilage. One well-documented change in OA cartilage is the induction of an activated cellular phenotype within the chondrocytes whereby matrix anabolism is strongly stimulated. Nevertheless, the chondrocytes fail to compensate for matrix damage induced externally (e.g., by mechanical stress or enzymatic degradation through synovial proteases). Additionally, the chondrocytes do play an active role in the degradative process themselves, a phenomenon termed *chondrocytic chondrolysis*.¹² During chondrocytic chondrolysis, OA chondrocytes activate or upregulate

TABLE 175.6

Differences between knee and ankle joint stability, motion, and cartilage

Feature	Knee	Ankle
Joint stability	Relatively unstable Noncongruent	Highly stable Highly congruent
Joint motion	Flexion/extension Rotation	Flexion/extension
Cartilage		
Cellularity	Same	Same
Cartilage thickness	2-6 mm	1-1.5 mm
Superficial chondrons	Single cells	Clusters of 2-4 cells
Sulfated glycosaminoglycan content	Lower	Higher
Water content	Higher	Lower
Collagen content	Same	Same
Dynamic stiffness	Lower	Higher
Hydraulic permeability	Higher	Lower
Peak stress with 65% final strain	11 MPa	16 MPa
Glycosaminoglycan synthesis		
In explants	Higher	Lower
In alginate	Same	Same
Proteoglycan half-life	22.68 days	16.58 days
Protein synthesis	Lower	Higher
IC ₃₀ for IL-1 reduction of proteoglycan synthesis		
In alginate	11 pg/mL	56 pg/mL
In explants	6 pg/mL	35 pg/mL
Influence of Fn-fs on		
Proteoglycan synthesis (antianabolic)	Low dose (1 nmol/L)	High dose (100 nmol/L)
Proteoglycan loss (catabolic)	Significant at 7 days	Not significant after 28 days
Attempted repair	No significant rebound	Significant rebound
Response to degeneration	Upregulation of collagen degradation	Upregulation of matrix synthesis

IC₃₀, concentration that inhibits 30%; IL-1, interleukin-1; MPa, megaPascals.

Fig. 175.10 In osteoarthritis (OA) chondrocytes are exposed to severely abnormal extracellular stimuli, including autocrine and paracrine factors, synovial factors, and altered matrix constituents, that induce a plethora of abnormal cellular responses made apparent by the changes in anabolism, catabolism, and phenotype that have been demonstrated in these cells. Also, chondrocyte numbers are modified by proliferation or apoptosis. In this schematic, an OA chondrocyte is embedded in a cartilaginous extracellular matrix of type II collagen, aggrecan, and fibronectin, for simplicity. Other collagens, proteoglycans, and noncollagenous proteins are also present at varying levels. (Reprinted with permission from Aigner T, Söder S, Gebhard PM, et al. *Mechanisms of disease: role of chondrocytes in the pathogenesis of osteoarthritis—structure, chaos and senescence*. *Nat Clin Pract Rheumatol* 2007;3:391-9.)

the expression of many matrix-degrading proteases such as the MMPs that are largely responsible for the breakdown of the collagenous and noncollagenous cartilage matrix components. This elevated proteolytic activity is not sufficiently counterbalanced by an increase in the chondrocyte anabolic activity. This is particularly true for the upper zones of damaged cartilage (the progression zone), in which the anabolic activity even drops again severely.¹³

Inflammatory signaling, reactive oxygen species, and reactive nitrogen species

Activation of proinflammatory (signaling) pathways and production of reactive oxygen and nitrogen species by chondrocytes appear to play a crucial role in OA disease progression. These occur independent of direct inflammatory cell infiltration within cartilage, with the chondrocyte acting as an

Fig. 175.11 One way to interpret cellular behavior in adult osteoarthritis (OA) is to investigate whether it shows similarities to developmental or evolutionary processes. Several processes that occur in OA are also known to have occurred during fetal chondrogenesis, including changes in the chondrocytic phenotype (differentiation), matrix anabolism and catabolism, (apoptotic) cell death, proliferation, and matrix calcification. The analysis of events during fetal development allows us to identify marker genes that can assist in the determination of the molecular context of a gene in the adult chondrocyte. For example, expression of SOX9 indicates differentiation to the chondrocyte phenotype, type IIA collagen (COL2A) is a chondroprogenitor cell marker, and type X collagen (COL10) is a marker of hyperplastic chondrocytes. Ki-67 indicates cell proliferation, whereas the onset of matrix metalloproteinase-13 (MMP-13) expression suggests increased matrix catabolism potentially linked to hyperplastic differentiation. Single-stranded DNA (ssDNA) indicates apoptotic DNA fragmentation, whereas aggrecan, COL2, COL9, and COL11 indicate anabolic cell activity (the synthesis of new cartilage matrix). Despite the appeal of a comparative approach, one should be cautious not to mistake uncoordinated degenerative processes for highly structured developmental processes. (Reprinted with permission from Aigner T, Söder S, Gebhard PM, et al. Mechanisms of disease: role of chondrocytes in the pathogenesis of osteoarthritis—structure, chaos and senescence. *Nat Clin Pract Rheumatol* 2007;3:391-9.)

Fig. 175.12 Anabolic and catabolic events in the growth plate of the primary ossifying skeleton are at least in part separated. Sox9 messenger RNA expression marks the zone of proliferation, which differs from the region of terminal chondrocyte maturation characterized by the expression of Ihh as a marker for the prehyperplastic chondrocyte and Col10A1 as a specific marker for the entire hyperplastic cartilage. MMP, matrix metalloproteinase. (Reprinted with permission from Aigner T, Gerwin N. Growth plate cartilage as developmental model in osteoarthritis research—potentials and limitations. *Curr Drug Targets* 2007;8:377-85.)

“inflammatory” cell. Proinflammatory signaling cascades are activated by diverse pathways, including Toll-like receptors, matrix degradation products, adverse mechanical loads, and action of classic inflammatory cytokines such as IL-1 and IL-6. Activated inflammatory pathways induce catabolic responses in chondrocytes with production of matrix-degrading proteases such as MMP-1, MMP-3, MMP-13, and ADAMTS aggrecanases and down-regulation of expression of the cartilage matrix components aggrecan and collagen type II. IL-1 affects gene expression patterns within articular chondrocytes via multiple intracellular pathways including the MAP kinases and nuclear factor- κ B pathways.^{14,15}

Because it is an avascular tissue, the partial pressure of oxygen is very low in cartilage, and chondrocytes live in a relatively hypoxic environment with an oxygen tension of around 6% at the joint surface to 1% in the deep layers of the articular cartilage. A major factor in chondrocyte adaption to hypoxia is the transcription factor hypoxia-inducible factor-1 α (HIF-1 α), which has key functions in controlling energy generation and cell survival, and even influences matrix synthesis.¹⁶ During normal oxidative metabolism reactive oxygen species (ROS) are formed as natural byproducts.¹⁷ They are involved in the control of a number of biologic processes including cell activation, proliferation, apoptotic cell death, and regulation of a wide variety of gene products, including cytokines, MMPs, adhesion molecules, and matrix components. In OA elevated production of ROS in combination with depletion of antioxidants leads to cellular or tissue oxidative stress. ROS may directly oxidize nucleic acids, transcriptional factors, membrane phospholipids, and intracellular and extracellular components, which leads to impaired biologic activity, cell death, and breakdown of matrix components. Significantly, ROS are a major cause of DNA damage within the genome. In addition to ROS, reactive nitrogen species (RNS) also are thought to be important in the pathogenesis of OA.¹⁸ RNS are derived from nitric oxide (NO), are produced in small amounts by nitric oxide synthase (NOS), and perform important functions in many physiologic processes. Increased expression of induced NOS as part of a proinflammatory responses results in increased production of NO and RNS. The mechanisms by which NO and RNS contribute to OA pathogenesis are being defined. NO has multiple effects on chondrocytes including inhibition of ATP production and matrix synthesis and promotion of cell death by caspase-3 and tyrosine kinase activation.

Obesity and adipokines

Being overweight is a strong risk factor for the development of OA in both weight-bearing and non-weight-bearing joints, which suggests roles for both biomechanical and systemic/metabolic factors.

The biomechanical hypothesis proposes that in obese patients increased weight results in excessive loading through weight-bearing joints that is over and above the physiologic range. Furthermore, abnormal gait and joint malalignment may affect stresses within and across joints in obese individuals, compounding the biomechanical problem. Although loading within a physiologic range is necessary for cartilage to remain healthy, excessive mechanical stress disrupts the homeostasis of the cartilage matrix. This occurs as a direct physical insult to the cartilage matrix, but in addition chondrocytes are able to sense mechanical loads through mechanoreceptors such as integrins that initiate intracellular signaling cascades, triggering a variety of cellular responses including the release of paracrine or autocrine factors. Within a physiologic range these mechanoreceptors induce anabolic activity, but with excessive loads proinflammatory and catabolic pathways are activated.

The association of obesity with hand OA, however, indicates an effect through mechanisms other than excessive or abnormal loading of joints. Therefore the systemic/metabolic hypothesis proposes that metabolic factors related to obesity act directly or indirectly on chondrocytes leading to the increased risk of developing OA.¹⁹ Several studies suggest that adipokines, proteins synthesized and secreted mostly by white fat adipocytes, are the major factors linking obesity to OA. Leptin, the prototypic adipokine, is present in OA cartilage and shows biologic activity on chondrocytes. It acts as a proinflammatory cytokine and a catabolic factor in cartilage metabolism via induction of MMPs.

A third (indirect) effect of obesity is certainly also the induction of a (latent) diabetic metabolic state in obese patients over time, which, for example, enhances formation of advanced glycation end products within the cartilage matrix with all their detrimental effects on matrix mechanical properties and cell behavior as discussed earlier.

The concept of progressive (apoptotic) cell loss

One of the simplest explanations for OA cartilage degeneration would be loss of viable chondrocytes due to cell death during the disease process.

Because chondrocytes are the only source of new matrix synthesis any significant cell loss would immediately result in a distortion of cartilage matrix homeostasis. Articular chondrocytes cannot self-renew, and cell loss would therefore be permanent and detrimental. Many studies have therefore addressed whether cell death plays a role in the pathologic process of OA.²⁰ Cell death can, in principle, be divided into apoptosis and necrosis. Apoptosis has evolved as a mechanism to eliminate surplus, abnormal, or dysfunctional cells whose survival and proliferation would be detrimental. Apoptosis is thus normally a beneficial process, although aberrant apoptosis can occur in pathologic states and apoptosis is clearly disadvantageous when it leads to the elimination of healthy cells. The presence of empty chondrocyte lacunae within cartilage matrix is a seemingly obvious histologic feature of OA cartilage.²¹ However, opinions on the prevalence and importance of chondrocyte death in OA pathologic changes differ widely,²² and most likely apoptotic cell death is a rather rare event.^{23,24} Also, lacunar emptying appears to be largely a technical artifact, mainly due to cell shrinkage except in late-stage disease where there is enhanced cell loss.²³

Apoptosis is a complex cellular process, and the factors responsible for apoptotic cell death in articular cartilage are largely unknown.²⁵ Because β_1 integrin-mediated cell matrix interactions provide survival signals for chondrocytes, reduction in extracellular matrix integrity due to degradation may be partly responsible for chondrocyte death *in vivo*. In cultured chondrocytes, treatment with Fas ligand (or anti-Fas), NO donors, tumor necrosis factor- α (TNF- α) or IL-1, taurosporin, ceramide, or retinoic acid has been shown to induce apoptosis, but it is uncertain which of these factors articular chondrocytes are sufficiently exposed to in the body. Certainly, chondrocytes become somewhat fragile if the pericellular matrix is removed or deranged²⁶ as in OA cartilage.^{27,28} In fact, degradation products of pericellular matrix components such as fibronectin might directly induce cellular death programs in chondrocytes.

Overall, the experimental evidence clearly suggests that apoptosis occurs in OA cartilage but at a very low rate, at least in the earlier stages. The relative contribution of apoptotic cell death to the pathogenesis of OA is difficult to assess because of the chronic nature of the disease process. Also, it is difficult to establish whether apoptosis is primary or secondary to cartilage matrix destruction. There is a good likelihood that, at least in later-stage disease, chondrocyte death and matrix loss form a vicious cycle, with the progression of one having promoting effects on the other.

The aging chondrocyte: genomic integrity and the chaotic phenotype

It has been known for a very long time that age is the most prominent risk factor for OA, but the explanations for this clear and strong association have changed over time.²⁹ In addition to continuing wear and tear, as cited in the classic hypothesis, the aging of matrix (see earlier) and cells are presumably very important etiopathogenetic factors for explaining this relationship.

The senescence theory of OA postulates that chondrocytes become senescent due to cellular stress and/or (focal) proliferation, which finally leads to a failure of the cells to fulfill their essential functions of maintaining proper matrix turnover. In general, cellular aging is associated with changes that undermine the ability of cells to maintain tissue homeostasis and culminate in cellular senescence. Replicative senescence occurs in cultures of continuously dividing somatic cell populations, including chondrocytes, after a limited number of population doublings and is due to telomere erosion. In postmitotic cells such as chondrocytes *in vivo*, progressive cellular senescence rather than replicative senescence appears to be important. Progressive cellular senescence is precipitated by steadily increasing damage to the genomic DNA, mostly secondary to oxidative stress. Oxidatively damaged molecules (DNA, proteins, lipids) accumulate with aging and gradually derange cellular functions.³⁰ Such molecules are normally removed and replaced during replication; however, this constant molecular renewal is not possible in postmitotic cells, and the oxidatively damaged molecules accumulate with time.

Substantial DNA damage and other cellular degenerative alterations are seen in OA chondrocytes.³¹ These effects would be expected to lead to apoptotic cell death in most cell types. Apoptosis appears to occur rather rarely in OA cartilage, however. Instead, the chondrocytes remain in a pre-apoptotic or para-apoptotic state with an uncoordinated pattern of gene expression, as shown in many *in-vivo* studies of chondrocyte behavior (Fig. 175.13). In this respect, the downregulation of molecules that are usually responsible for regulating cell integrity and/or removal after nonacceptable cell damage may be an important permissive factor at this stage. For example, the expression of the small guanosine triphosphatase RhoB, a molecule that is constitutively expressed by normal articular chondrocytes, is significantly downregulated in OA cartilage.³² RhoB is involved in cytoskeletal

organization, cell transformation, and survival but, most importantly, appears to be required for the apoptotic response, at least in some cell types. One intriguing speculation is that the downregulation of RhoB in OA chondrocytes might be a prerequisite for the sustained preapoptotic or paraapoptotic phenotype of OA chondrocytes despite the substantial DNA damage that in normal cells would lead to apoptotic cell death.

Aging does not inevitably lead to OA, and not all aged chondrocytes show loss of function. Nevertheless, even in the “normal” joints of elderly people the cartilage no longer looks juvenile. The major difference between normal aged cartilage and OA cartilage is that, in the former, lesions do not progress and do not result in symptomatic disease. Although all individuals are susceptible to the same age-related changes, these appear to progress faster in some individuals (e.g., patients with primary OA) than others. Thus OA shows “premature” or accelerated degeneration of articular cartilage due to a premature senescence of the chondrocytes that maintain its structural integrity. By analogy to neurodegenerative disorders one could call OA the “morbus Alzheimer” of articular cartilage and chondrocytes.²⁹ This analogy is particularly intriguing because OA chondrocytes, and to a lesser extent aged chondrocytes, show discoordinate reaction patterns (see Fig. 175.13),³⁰ which are most likely related to a disturbance of the “cellular brain,” the gene regulation machinery. Also, cartilage and brain share an important similarity: both have “(very) old,” largely postmitotic cells (i.e., basically no cell supply and proliferation after puberty) and thus show hardly any

regeneration capacity. However, cartilage has an additional problem in that it lacks the plasticity of the neuronal network. A functionally intact chondrocyte cannot adequately replace a dysfunctional chondrocyte located at a distance from it. Additional research is needed to determine whether accelerated cell aging processes account for the phenotype of the disease or, as is the case in Alzheimer disease, there are additional features that would allow one to take new therapeutic approaches. Even if cell aging is an inevitable feature of OA (e.g., for limiting tumorigenic capacity), these processes can be used to identify and manipulate the causes of premature chondrocyte degeneration.

The synovial membrane

The two main clinical symptoms of OA, pain and stiffness, are both significantly related to synovial inflammation and capsular fibrosis. Although its clinical importance is clear, however, the role of synovial inflammation in the pathogenetic process of cartilage destruction remains largely unknown (Fig. 175.14).³³ The synovial (inflammatory) reaction observed in OA joint disease has been considered primarily to be a secondary effect resulting from the release of cartilage debris from the damaged articular cartilage. This is in contrast to the situation found, for example, in rheumatoid arthritis, which is considered to originate from a synovial inflammatory autoimmune reaction with secondary cartilage destruction. However, inflammatory

Fig. 175.13 Articular chondrocytes in the normal joint behave in a very structured manner: they react to extracellular stimuli (e.g., joint loading, matrix changes, and exposure to cytokines and growth factors) according to their internal, predetermined program. In cartilage degeneration in osteoarthritis (OA), chondrocytes are exposed to abnormal stimuli such as nonphysiologic loading conditions, byproducts of matrix destruction (e.g., fibronectin and collagen fragments), and cytokines and growth factors that are not normally expressed in cartilage. This exposure leads to structured/deterministic cellular reactions, some of which are functionally positive for the tissue (e.g., anabolism) and others of which are dysfunctional or detrimental (e.g., increased matrix catabolism and cell death). Potentially even more problematic for preserving tissue homeostasis are the unstructured/stochastic reaction patterns typically seen in OA chondrocytes, which lead to a significant microheterogeneity of cellular reaction patterns.

Fig. 175.14 In osteoarthritis (OA), molecular detritus from the cartilage activates the synovial lining cells. The synovial lining cells produce cytokines, growth factors, and (latent) enzymes. Synovial cell-derived cytokines and growth factors further activate the chondrocytes. Enzymes produced by the synovial lining cells can directly degrade matrix molecules if not inactivated by inhibitors in the synovial fluid. Latent enzymes can be activated in the milieu of the OA cartilage. ADAMTS, a disintegrin and metalloproteinase with thrombospondin type 1 motif; BMP, bone morphogenetic protein; IL-1, interleukin-1; MMP, matrix metalloproteinase; TIMP, tissue inhibitor of metalloproteinases; TGF-β, transforming growth factor-β; TNF, tumor necrosis factor. (Reprinted with permission from Aigner T, van der Kraan P, van den Berg W. Osteoarthritis and inflammation—inflammatory changes in osteoarthritic synoviotherapy. In: Buckwalter JA, Lotz M, Stoltz JF, editors. Osteoarthritis, inflammation and degradation: a continuum. Amsterdam: IOS Press; 2007, p. 219-30.)

reactions in the synovial membrane do occur to some degree in all OA joints. Also, the fact that most OA patients display a minor elevation of serum C-reactive protein level suggests that the inflammatory component plays some role in the disease process.

Synoviocyte activation and proliferation as well as synovial hyperplasia presumably all represent reactive changes in response to increased demands for clearance of molecular debris in the synovial fluid of the joint. Although a cellular inflammatory component is missing in particular cases of early OA, synovial hyperplasia and activation is likely to generate significant problems for articular cartilage homeostasis. Synoviocytes are able to secrete not only matrix-degrading proteases (e.g., MMPs) but also catabolic cytokines and growth factors (e.g., IL-1, TNF- α) as well as ROS/NOS-inducing inflammatory and catabolic signaling pathways within chondrocytes.

The subchondral bone

A debate continues as to whether the changes in subchondral bone are a cause or a consequence of changes in the overlying cartilage. It is likely that both are true. In some instances altered structure of the subchondral bone will lead to secondary changes in the cartilage, whereas in other situations changes in subchondral bone will be adaptive in response to altered mechanical loads as cartilage deteriorates. In established OA increased thickening of the subchondral bone plate (compare Fig. 175.4f with normal bone shown in Fig. 175.4c) and changes in the architecture of subchondral bone trabeculae result in radiologically distinctive osteosclerosis. Subchondral bone sclerosis occurs as a modeling/remodeling response to the increased mechanical loads that are transmitted to the bone as a consequence of altered biomechanics within the joint and cartilage loss. The trabecular bone volume increases by around 20% due to an increase in the number of bone trabeculae and reduced separation between trabeculae, rather than through thickening of the trabeculae. Because the new bone formed is less mineralized than normal bone, although there is an increase in apparent density, the material density of the bone is significantly reduced.

Subchondral bone cysts usually occur deep to areas in which the overlying cartilage has been completely lost. Subchondral bone cysts are histologically diverse, consisting of pools of mucoid material or reparative mesenchymal tissue showing variable degrees of fibrous and fibrocartilaginous differentiation. There is usually evidence of new bone formation and remodelling at the periphery of the cysts, but the cysts themselves do not normally contain bone—hence their radiolucency. Bone marrow lesions are areas of ill-defined bone marrow hyperintensities seen on T2-weighted magnetic resonance images in patients with OA. Histologic studies indicate that these are areas of localized bone and marrow necrosis with fibrosis and reparative changes. Some may progress to bone cysts. Bone marrow lesions are associated with pain in OA patients, and at least in moderate to advanced lesions, the changes in the subchondral bone represent an interesting target tissue for symptomatic treatment in these patients.

Influence of mechanical load

Mechanical loading within a physiologic range maintains joint tissues and cartilage in a healthy state. Mechanical loading that is either below or in excess of the physiologic range causes cartilage degeneration. For this reason, abnormalities of mechanical loading are central to the development of OA. OA arises when there is an imbalance between the mechanical forces within a joint and the ability of the cartilage to withstand these forces. This arises in two situations. In the first, normal articular cartilage is exposed to abnormal mechanical loads, whereas in the other, the articular cartilage is fundamentally defective with biomaterial properties that are insufficient to withstand normal load bearing.

The mechanisms by which mechanical loads influence cartilage structure are beginning to be understood (see Chapter 8). Chondrocytes sense and respond to mechanical stimuli transmitted through the matrix. The mechanical forces are recognized by mechanoreceptors such as integrins and stretch-activated ion channels. Activation of these transmembrane molecules by physiologic mechanical loads results in stimulation of a series of regulatory molecules and intracellular signal cascades including FAK, PKC, JAK/STAT and MAP kinases that ultimately leads to changes in gene expression and protein production. Thus an anabolic response is produced that maintains, and in some circumstances improves, cartilage structure and function. The particular cascade stimulated depends on the mechanoreceptor activated and the involvement of downstream autocrine and paracrine activity. Anabolic responses resulting in increased expression of aggrecan and inhibition of protease production involve $\alpha_5\alpha_1$ integrin and release of locally acting mediators that include interleukin-4 and substance P.³⁴ In contrast, overloading induces a stress response with molecular and biome-

chanical changes that shift the balance of tissue remodeling in favor of catabolic over anabolic activity. Although these events also appear to be integrin mediated, the molecules involved and pathways activated are different from those seen when cartilage is physiologically loaded. Stimulation of stress-induced intracellular pathways leads to the production of proinflammatory cytokines such as IL-1 and TNF- α and increased production of MMPs and aggrecanases. Interestingly, chondrocytes from OA cartilage show an altered responsiveness to mechanical loads because they fail to show an anabolic response to physiologic loading but instead demonstrate a proinflammatory IL-1 β -dependent response. This may further accelerate disease progression and attenuate cartilage repair.

Neuromuscular function and proprioception—roles in joint homeostasis

Joint stability depends on several neuromuscular factors, including the strength and coordination of the joint-related muscles as well as proprioception (the ability to sense the position and movement of the limb).³⁵ The association of weak quadriceps femoris with radiographic and symptomatic knee OA is most likely due to loss of joint stability and abnormal loading on movement. Thus muscle strengthening seems to have a preventive effect for OA. Whether the knee joint benefits from quadriceps strengthening after the onset of OA is unclear. Proprioception is also important for joint stability. Proprioception relies on specialized nerve endings, mechanoreceptors, which are located in the muscles and the ligaments and are essential for fine tuning of muscular movement. Proprioception declines with age, and a further decrease is seen in patients with OA. However, it is unclear whether impaired proprioception in OA contributes to or results from the disease.

GENETICS, FUNCTIONAL GENOMICS, AND EPIGENETICS

Genetics

OA, like nearly all other diseases, is initiated and progresses dependent on the genetic background of the individual. Therefore the potential of genetics for elucidating the pathogenesis of OA has been the subject of intensive investigation for years (see Chapter 176). However, overall pathogenetic concepts based on genetic data are missing, and the overall ability of the genetic information to explain OA development is rather limited. One major difficulty is to separate genes that influence the development of the joints (thus resulting, e.g., in abnormal joint shape and biomechanical weakness) from genes that lead to an insufficiency of the cells to maintain adequate repair and joint homeostasis later in life, which are relevant for preventing and treating OA.^{36,37} Another reason for the complexity of the interpretation of genetic data is that many of the genes detected are likely to be linked to processes in other organ systems such as neuronal cross-linking, muscle strength, and mental perception. All these have roles in OA development and disease manifestation without being related to cartilage physiology and pathobiology.

It has been known for some time that OA “runs in families,” but to what extent this is due to shared genetic influences or shared family environment is still uncertain. The disease is clearly multifactorial and polygenetic; that is, it results from the interaction of several, possibly many, genes. Overall, the relevance of the genetic aspects of OA joint disease is still under debate, presumably also because of the considerable heterogeneity of the genetics of OA. Also, it seems that different combinations of different susceptibility genes may apply to different forms of OA,³⁸ and in fact different classes of mutated genes lead to different types of early- and late-onset OA.³⁶

Functional genomics and proteomics

One major change in OA research in recent years has been the shift from investigating primarily biochemical aspects of articular cartilage matrix destruction to studying the molecular aspects of the disease process. It is the molecular phenotype of the resident chondrocytes that determines the homeostasis of the cartilage matrix. The cellular reaction pattern of the chondrocytes in OA cartilage degeneration is poorly understood, however, mainly because many of the involved genes have not yet been identified and characterized. Such gene profiling is precisely one of the strengths of gene expression chip technology.³⁹ In fact, many studies have been performed during the past decade using the array-chip technology, and quite a few interesting genes and gene clusters have been found; these included, in addition to known candidate gene groups such as anabolic and catabolic

genes, new gene networks such as a cluster of oxidative defense genes (e.g., the gene for superoxide dismutase-2 [SOD2], the major mitochondrial ROS scavenger) and others. Further studies must validate the relevance of these findings for understanding and manipulating these molecular networks in the context of OA. These attempts will be supplemented by proteomics, which will reveal an even more complex pattern.⁴⁰

Epigenetics

Clearly, one major issue during disease progression is a severe alteration of the gene expression phenotype of the articular chondrocytes. Besides gene regulation by ordinary transcription factors, epigenetic gene regulation may play an important role in determining gene expression levels; namely, methylation of genes coding for cytokines, growth factors, and so on.^{41,42} First experimental data indicate that differences in the methylation status within disease-relevant promoters are likely to induce or repress respective gene expression.⁴³ This is not true for all genes, however. Thus, for example, no changes were found in the methylation levels of the aggrecan gene in aged and diseased chondrocytes.⁴⁴ The overall genomewide methylation level remains unchanged in normal and in diseased and aged chondrocytes,

although this does not exclude differences in methylation levels for selected promoter regions. Altogether, the data are sparse so far. The implications of epigenetic dysregulation in OA chondrocytes remain open for future investigations. Also, the effects of alterations in micro-RNA expression in OA chondrocytes represent a new and exciting but still unresolved issue.^{42,45}

CONCLUSION

OA is a disease of the diarthrodial joint, with the gross and microscopic pathologic changes being seen in all joint tissues, although changes in articular cartilage are still thought to be paramount in the disease. The risk factors that predispose to the development of OA, such as increasing age, obesity, mechanical loading, and genetics, have been known for some time, and we are now beginning to understand how these may influence normal joint structure and function and predispose to OA. New insights into the cellular, biochemical, and molecular changes in the tissues of the synovial joint with the onset and progression of OA as it arises under different clinical scenarios may at last indicate novel routes by which this debilitating disease can be treated or prevented.

Genetics of osteoarthritis

■ ANA M. VALDES ■ TIM D. SPECTOR

- Osteoarthritis (OA) has an important genetic component, which has been explored in humans both in monogenic syndromes and in its complex common form.
- Monogenic studies have identified mostly extracellular matrix-related genes, whereas genomewide association and candidate gene studies have revealed the complexity of OA, with many genes contributing modestly to overall disease risk.
- The contribution of genetics to the common OA form has now been estimated to be on the order of 39% to 65%, and first-degree relatives of individuals with OA have a twofold to threefold increased risk of disease.
- Several of the genes identified appear to relate to skeletal development mediated by bone morphogenetic proteins (*ASPN*, *SMAD3*, *GDF5*) and Wnt signaling (*DOT1L*); other genes are known to be related to cartilage metabolism (*CHST11*).
- The functional role of many of the genes identified still remains to be elucidated.

INTRODUCTION

The multifactorial nature of osteoarthritis (OA) is well recognized, and a number of environmental risk factors such as obesity, previous injury, and meniscectomy are strongly associated with its development.¹ The role of genetic factors in the development of OA has received considerable attention, aided by our rapidly expanding knowledge of molecular biology. This chapter reviews the data that support the role of genetic variation in the common, as well as rare, forms of OA.

EVIDENCE FOR INHERITANCE OF OSTEOARTHRITIS

A strong genetic component to certain forms of OA has been recognized for more than 60 years. In 1941 Stecher² demonstrated that Heberden nodes of the fingers were three times more common in the sisters of 64 affected individuals than in the general population. Subsequently, in 1944 Stecher and Hersch^{2a} concluded that these lesions were inherited as a single autosomal dominant gene with a strong female predominance.

The most common form of inherited OA is primary generalized OA, which was first described as a clinical entity by Kellgren and Moore in 1952.³ This form is characterized by the presence of Heberden and Bouchard nodes and premature degeneration of articular cartilage, often in a concentric pattern in many joints. Subsequent studies provided additional evidence for the familial occurrence of Heberden and Bouchard nodes and of OA involving multiple joints. In a study of 391 cases of OA, 120 mostly middle-aged women were identified as having a polyarthritis characterized by signs of inflammation and acute onset of symptoms. Of these patients, 20% gave a family history of similar joint disease.³ This and other studies suggested a polygenic form of inheritance rather than a single gene defect in primary generalized OA.³

TRAITS AND OUTCOMES STUDIED IN THE GENETICS OF OSTEOARTHRITIS

In both epidemiologic and genetic studies the definition of OA that is used most often is a radiographic one, usually based on the Kellgren and Lawrence grade.⁴ In addition, several studies have focused on “clinical OA” defined as radiographic OA plus the presence of pain, some have used the American College of Rheumatology classification criteria for OA, and some studies have used total joint replacement with a primary indication of OA as a surrogate for severe clinical OA.⁵ It is worth noting that OA represents a group of disorders with distinct risk factor profiles and disease courses.^{4,6,7} To separate and define these subphenotypes, it is therefore desirable to investigate the components that define different forms of OA, such as radiographic severity, extent of cartilage loss, presence or absence of synovitis, pain and functional severity of the disease, and generalized versus non-generalized disease, among others. The genetic contribution to some of these factors is only beginning to be addressed.

TWIN AND FAMILY STUDIES

Twin studies

Comparing the resemblance of identical twins with regard to a trait or disease with the resemblance of nonidentical twins offers the first estimate of the extent to which genetic variation determines variation in that trait, or heritability. The heritability of OA has been calculated in twin sets after adjustment of the data for other known risk factors such as age, sex, and body mass index. Such findings show that the influence of genetic factors in radiographic OA of the hand, hip, and knee in women is between 39% and 65%, independent of known environmental or demographic confounding factors. Classical twin studies and familial aggregation studies have also investigated the genetic contribution to cartilage volume and progression of disease (e.g., research by Zhai and colleagues^{8,9}). A comparison of the similarities in identical and nonidentical twins allows one to estimate the extent to which genetic factors determine variation in the measures of OA. Examples of OA traits whose heritability has been assessed using a twin study design are presented in Table 176.1.

Familial aggregation studies

Analysis of familial aggregation is the sine qua non for continuing the genetic analysis of a disorder, and several studies have reported the risk ratio for a relative of an affected individual compared with the population prevalence (λ s). A study in Nottingham¹⁰ assessed the prevalence of hip OA in siblings of individuals undergoing total hip replacement (THR) compared with the prevalence of radiographic hip OA in individuals undergoing intra-venous urograms for investigation of a renal problem (i.e., control subjects). This study reported a λ s of 4.99 for Kellgren and Lawrence grade III or higher, a λ s of 5.01 for a minimum joint space width, and a λ s of 8.53 for THR. A similar study by the same group was carried out using total knee replacement (TKR) as the selection criterion¹¹ and reported a λ s of 2.13 for tibiofemoral OA and 2.08 for any radiographic knee OA. Use of self-reported total joint replacement in a smaller data set¹² resulted in a λ s of 1.87 for THR and a λ s of 4.81 for TKR. More recently a U.S. study carried out a similar analysis and reported λ s values of 2.85 for THR and 2.92 for TKR, although the familial aggregation for TKR did not remain statistically significant after adjusting for age and sex.¹³ Familial aggregation of specific knee OA phenotypes such as anteromedial OA that correspond to lesions

in the tibial plateau and preservation of cartilage of other compartments of the knee have also been reported in UK populations.¹⁴ Unlike other patterns of OA, cartilage degeneration in anteromedial OA is consistent with increased loading and thus might be assumed to be due mostly to mechanical causes, rather than genetic factors. Yet the λ s of 3.21 reported for this form of OA suggests a substantial genetic contribution for this particular type of OA as well.

FAMILIAL DISORDERS ASSOCIATED WITH OSTEOARTHRITIS

Some characteristics of OA resemble chondrocyte differentiation processes during skeletal development by endochondral ossification.¹⁵ Based on this observation, it has been proposed that signaling molecules regulating chondrocyte activity in growth cartilage may also be involved in OA pathogenesis.¹⁵ Endochondral ossification is initiated by the formation of cartilage templates of future bones, built by mesenchymal progenitor cells, which differentiate into chondrocytes. The differentiated cartilage cells undergo a cascade of late differentiation events culminating in chondrocyte hypertrophy. After invasion of blood vessels from the subchondral bone, the majority of hypertrophic cells undergo apoptosis, and the cartilage template is remodeled into trabecular bone.¹⁵ Similarly, proliferation of chondrocytes, hypertrophic differentiation of chondrocytes, remodeling and mineralization of the extracellular matrix, invasion of blood vessels, and apoptotic death of chondrocytes occur during OA.

The similarities in the pathologic progression of the disease, even when the initiating events are different, suggest that there may be a common

molecular sequence of events underlying OA progression. Therefore it has been a major emphasis to understand rare monogenic skeletal disorders that resemble OA to understand the molecular basis of OA.¹⁶

Premature OA is in fact part of the pathologic processes associated with many mutations affecting cartilage extracellular assembly or stability, such as Stickler syndrome type I, multiple epiphyseal dysplasia, and osteochondritis dissecans.

A large number of other disorders influencing skeletal development exist but are not discussed here because they are not OA-like and do not result in early-onset OA. The following is only a brief summary, and for more detailed information the reader is referred to other chapters in this book dealing with monogenic disorders of skeletal development and to the review by Warman and coworkers.¹⁷ A partial list of monogenic disorders that display OA or OA-like syndromes is presented in (Table 176.2).

NATURE OF THE GENETIC INFLUENCE IN OSTEOARTHRITIS

Linkage studies

Genetic linkage is observed when the genetic markers and the disease locus map relatively close to each other on the same chromosome. If family data are available, genetic markers can be used as tools to dissect the inheritance pattern of a gene involved in a specific trait or disease. For example, pairs of siblings who both are affected with OA have been used to identify chromosomal regions harboring OA genes. The higher the proportion of alleles identical by descent that sibs concordant for OA share at a given marker, the closer that marker is to an OA-related gene. Several genome-wide linkage studies have been conducted in humans to identify quantitative trait loci (QTLs) for OA. Hunter and colleagues¹⁸ reported four significant linkage regions for the hand (logarithm of odds of linkage [LOD] score, 3 or higher) when the individual joints were treated separately, which suggests that a splitting rather than a lumping approach may be more successful.

Livshits and colleagues,¹⁹ using twin sib pairs, have shown a replication of QTLs on chromosome 2 (LOD score, 2.9) and chromosome 19 (LOD score, 4.26) for hand OA. A genome-wide linkage scan was done to identify susceptibility loci for total hip replacement, using DNA from a large Icelandic family with a high prevalence of primary hip OA; a locus with an LOD score of 2.58 was identified on chromosome arm 16p.²⁰ A similar locus mapping to chromosome 16 was reported in a study from the United Kingdom.²¹ This is the first instance in which what may be the same susceptibility locus for OA has been independently described in two different populations with hip OA. Linkage studies, although of use for investigation of monogenic conditions, are of limited value for common OA because the genomic regions identified are very large and depend on subsequent fine mapping, which is done by genetic association methods.

TABLE 176.1
Heritability of various osteoarthritis-associated traits derived from twin studies

Trait	Heritability (h^2)	Study
Radiographic knee osteoarthritis	39%	Spector et al ⁴⁴
Radiographic hip osteoarthritis	60%	MacGregor et al ⁴⁵
Femoral cartilage volume	61%	Hunter et al ¹⁸
Tibial cartilage volume	76%	Hunter et al ¹⁸
Patellar cartilage volume	66%	Hunter et al ¹⁸
Change in knee joint space narrowing grade	74%	Zhai et al ⁹

*Only variants for which replication studies were carried out and with an overall sample size of >1000 are included.

[†]Allele unless otherwise indicated, can be haplotype or genotype.[‡]Refers to a specific haplotype in a recessive mode.[§]Only women.

SNP, single nucleotide polymorphism; TGF, transforming growth factor.

Candidate genes

Candidate gene association studies rely on a-priori understanding of the cause of OA and allow only very small regions of the genome to be targeted for investigation. Consequently many important genes have probably been overlooked using this method. Notwithstanding, candidate gene studies have identified a number of important genes such as *ASPN*, *FRZB*, and *PTGS2* that continue to be compelling targets for functional studies and further genetic replication in independent populations.

The candidate gene association method identified the polymorphism rs143383 within the 5' untranslated region [UTR] of the gene *GDF5*. This is still the most robustly replicated polymorphism to be associated with OA and the only locus to replicate successfully across diverse Asian and European populations. Although very few genes meet the strict criteria of replication, even fewer have also demonstrated functional significance. Among these, some of the most compelling are the asporin gene *ASPN*,²² the *GDF5* gene encoding growth differentiation factor 5,^{23,24} and the *SMAD3* gene.²⁵ These three genes have in common being part of the bone morphogenetic protein (BMP) signaling pathway (Table 176.3). Another interesting gene identified first by linkage analysis and later by association is the deiodinase iodothyronine type II gene (*DIO2*).²⁶ *DIO2* encodes an intracellular enzyme in the thyroid hormone pathway responsible for the local bioavailability of thyroid hormone in specific tissues, including the growth plate. The active thyroid hormone triiodothyronine plays an essential role in the control of chondrocyte proliferation and differentiation, inhibiting BMP-2-induced growth of mouse rib. More recently it has been shown that carrier status at one of the *DIO2* markers identified initially, rs12885300, is significantly associated with a specific hip shape.²⁷ Because nonoptimal joint geometry is a risk factor for the development of OA, this result suggests that the role of *DIO2* in hip OA is mediated, at least in part, by an effect on joint geometry.

Selected candidate genes associated with OA are shown in Table 176.3. The selection criteria for these associations were the following: they are genetic variants for which data were available from at least one replication cohort, and the P value had been adjusted for multiple testing and conferred nominal significance of at least $P < .0005$. This P value cutoff for candidate genes represents the level needed to achieve 80% Bayesian posterior credibility for a genetic association that has a prior probability of being true of 10%.²⁸

Genomewide association studies

With the advances in high-throughput single nucleotide polymorphism (SNP) genotyping technology, genomewide association studies (GWASs) have become possible in the past 5 years. These studies take advantage of linkage disequilibrium (LD), that is, the fact that in any given chromosomal region in the genome alleles at physically nearby loci are associated in the population. The markers analyzed need not be functional but may simply be in LD with the functional variant.²⁹ However, the large-scale nature of these studies introduces a multiple testing issue, which makes the need for

very large sample sizes or replication of any positive associations an absolute requirement. GWASs are nevertheless a powerful approach for unlocking the genetic basis of complex diseases such as OA. Individual studies may be hampered by sample size limitations, which result in lack of statistical power, and meta-analyses based on consortium efforts may help overcome some of these limitations.

Several GWASs for OA have been carried out (Table 176.4). Initially, small-scale studies of sparse maps of approximately 100,000 SNPs were reported that used small discovery populations and larger-scale replication populations. Such a study found DVWA (double von Willebrand factor type A domain) to be associated with OA in Asian populations.²² Later a UK GWAS using pooled DNAs from 357 cases and 285 controls reported the identification of a signal (rs4140564) between *PTGS2* and *PLA2G4A*.³⁰

In 2010 results from three GWASs for OA were published: the Rotterdam and arcOGEN (Arthritis Research Campaign Osteoarthritis Genetics) studies in the Netherlands and United Kingdom, respectively, and a third in Japan. The Japanese study used a standard approach employing 899 cases and 3396 controls. Replication increased the size to 1879 cases and 4814 controls. Two SNPs located within a small region of the HLA locus on chromosome arm 6p were identified to be associated with knee OA ($P < 7 \times 10^{-8}$).³¹ However, replication was not achieved in either of two European cohorts or, surprisingly, in a population of Han Chinese.³² A subsequent large-scale replication study encompassing 36,408 control subjects and 5749 knee OA patients of European descent found that the SNPs identified by Nakajima and coworkers were conclusively not associated with OA in European populations.³³ The same study showed that in Japanese individuals these SNPs are in strong LD ($r^2 = 0.86$) with the HLA class II haplotype DRB1*1502 DQA1*0103 DQB1*0601 (frequency in Japanese, 8%) which would be protective for knee OA. In white and Chinese samples, the SNPs identified by the Japanese GWAS are not in LD with that haplotype ($r^2 < 0.07$), and the HLA haplotype in question is also much rarer (0.8 % and 2.3% of individuals, respectively) than in Japanese. Thus, although the HLA class II region may be implicated in risk of knee OA, the results to date do not allow a generalization to European populations.³³

As for the GWASs in samples of European descent, the GWAS in Rotterdam also used a relatively small discovery cohort of 1341 cases and 3496 controls from the Netherlands. Replication involved additional European cohorts and North Americans of European descent. This produced a respectably powered study of 14,934 cases and 39,000 controls. A signal ($P < 8 \times 10^{-8}$; odds ratio [OR], 1.14) was identified in a region on chromosome band 7q22 that included a large LD block extending over 500 kilobases [kb] associated with knee and hand OA. The addition of several more cohorts to the original study increased the evidence for the veracity of this signal. However, the LD block contains six known genes, all of which are equally good candidates for association with OA. These include *PRKAR2B*, encoding cyclic adenosine monophosphate-dependent protein kinase regulatory subunit type II- β ; *GPR22*, encoding G protein-coupled receptor 22; and *COG5*, encoding component of oligomeric Golgi complex 5. Additional investigation intriguingly revealed an expression QTL within *GPR22* in high LD with the identified association signal.³⁴ A subsequent meta-analysis that

arcOGEN, Arthritis Research Campaign Osteoarthritis Genetics; SNP, single nucleotide polymorphism; THR, total hip replacement; TKR, total knee replacement.

encompassed 6709 cases of knee OA cases and 44,439 controls showed conclusively that this signal is associated with genomewide significance in samples of European descent (OR, 1.17; 95% confidence interval [CI], 1.11 to 1.24; $P = 9.2 \times 10^{-9}$) but not in Asian populations (OR, 1.03; 95% CI, 0.85 to 1.25; not significant).³⁵

Finally, the arcOGEN study was conducted by a UK-based consortium involving seven collection centers. The discovery cohort consisted of 3177 cases and 4894 controls, and replication of signals involved additional European cohorts as well as white North Americans, resulting in an overall meta-analysis sample of 13,768 cases and 53,286 controls. This GWAS was unable to identify a signal of genomewide significance. This disappointing result highlights the difficulty in finding OA genes even when a study is adequately powered. It points to the fact that there are probably many genes contributing to OA, all of which individually have very modest genetic effect.³⁶ Using these same GWAS data UK scientists have generated 1000 Genomes Project–based imputation³⁷ on the same data from the arcOGEN consortium as earlier (3177 knee and hip OA cases and 4894 population controls). The resulting imputed genotypes were then used to detect previously unidentified risk loci. Through large-scale replication it was possible to establish robust association with SNPs in the MCF2 cell line–derived transforming sequence-like gene (*MCF2L*).³⁸ The top signal, rs11842874, reached a combined OR of 1.17 (95% CI, 1.11 to 1.23; $P = 2.1 \times 10^{-8}$) across a total of 19,041 OA cases and 24,504 controls of European descent.

MCF2L is a rho-specific guanine nucleotide exchange factor. In human cells MCF2L regulates neurotrophin-3–induced cell migration in Schwann cells.³⁹ Although this might potentially supports the relevance of nociceptive molecular pathways in genetic susceptibility to OA, Valdes and coworkers⁴⁰ have reported an association between the MCF2L gene variant and radiographic severity at the patellofemoral knee compartment. Thus further research into the role of this gene in OA pathogenesis is necessary.

In the arcOGEN study a second GWAS was conducted in 7410 patients with severe OA, 80% of whom had undergone total joint replacement, and 11,009 unrelated controls from the United Kingdom.³⁷ The most promising signals were replicated in an independent set of up to 7473 cases and 42,938 controls from studies in Iceland, Estonia, the Netherlands, and the United Kingdom. This study has identified several new genetic loci associated with large joint OA (see Table 176.4) which are discussed here.

The most significant association signal resided on chromosome 3 and was followed up by two SNPs in perfect LD with each other: rs11177, a missense polymorphism within exon 3 of *GNL3*, coding for nucleostemin

(OR, 1.12; 95% CI, 1.08 to 1.16; $P = 1.25 \times 10^{-10}$); and rs6976, situated in the 3' UTR of the *GLT8D1* gene. Interestingly, the authors also reported that whereas nucleostemin was barely detectable in cultured chondrocytes from control subjects it was clearly detectable in cultured chondrocytes from OA patients and was significantly upregulated in OA compared with control chondrocytes.

All of the remaining four signals with genomewide significance emanated from cases with hip OA: rs4836732, located within intron 18 of the *ASTN2* gene (OR, 1.18; 95% CI, 1.12 to 1.25; $P = 2.42 \times 10^{-9}$); rs9350591, located 38 kb upstream of *FILIP1* and 70 kb upstream of *SENP6*; rs10492367 (OR, 1.14; 95% CI, 1.09 to 1.20; $P = 1.48 \times 10^{-8}$), 59 kb downstream of *KLHDC5* and 96 kb downstream of *PTHLH*; and rs835487 (OR, 1.13; 95% CI, 1.09 to 1.18; $P = 1.64 \times 10^{-8}$), located within intron 2 of *CHST11*. Three additional signals approached genomewide significance: rs12107036 was associated with OA in females who had undergone TKR and resides within intron 12 of *TP63*; rs8044769 was strongest in the female OA stratum (allele C OR, 1.11; 95% CI, 1.07 to 1.15; $P = 6.85 \times 10^{-8}$) within intron 1 of *FTO*; and, in the male OA stratum, rs10948172 (OR, 1.14; 95% CI, 1.09 to 1.20; $P = 7.92 \times 10^{-8}$), situated in the vicinity of the *SUPT3H* gene.⁴¹ For the most part the role of these molecules in OA pathogenesis remains to be elucidated.

A different approach was used by Castaño Betancourt and colleagues,⁴² who, rather than concentrating on OA phenotype itself, carried out a GWAS on cartilage thickness in the Rotterdam study and identified a SNP in the *DOT1L* gene that was strongly associated with minimum hip joint space width on radiographs.⁴² This result was replicated in independent cohorts in the United Kingdom and overall achieved a genetic effect size (expressed as the regression coefficient β) of 0.09 mm per allele ($P = 1.1 \times 10^{-11}$). The allele associated with larger minimum hip joint space width was found also to be strongly associated with decreased risk of hip OA (OR, 0.88; 95% CI, 0.82 to 0.94; $P = 1.1 \times 10^{-4}$). Experimental work by the same authors showed that this gene plays a role in chondrogenic bone development via regulation of Wnt signaling.⁴²

Although GWASs have proved to be a great success in investigating some traits and have overcome many of the reliability problems encountered in earlier analytic methods, they have attracted criticism. Not least among the complaints is the vast resources required to undertake such a study. Moreover, the analysis of hundreds of thousands of SNPs dictates that the level of significance needs to be lowered to reflect the multiple testing inherent in such analysis. The genomewide significance threshold required to

consider a genetic variant as “true” is $P < 5 \times 10^{-8}$, which places a considerable burden on investigators because it necessitates using very large sample sizes or detecting only variants with a relatively large effect size (which is not seen in common diseases such as OA). This means that many true signals are potentially being overlooked. This α level, combined with the knowledge that many signals have very modest genetic effects of between 1.1 and 1.2, has required that the sample sizes of these studies be increased substantially to tens of thousands of cases to identify the associated signals successfully.

It should be noted, however, that the existence of low effect sizes is not limited to genetic studies of OA or other common traits. At the same time, GWASs, by setting strict rules on the selection of cases and controls and on the significance threshold, which is put at the level of $P < 5 \times 10^{-8}$, have considerably raised the quality of genetic studies and drastically diminished the rate of false-positive reporting. GWASs have strongly highlighted the need for replication of findings, supporting the requirement for collaborative efforts. Large genetic consortia in Europe and the United States are already facilitating these kinds of collaborations in OA.

Finally, criticisms of GWASs have grown with their very success. With the ever-increasing numbers of identified signals for each of the common traits under investigation, it has been noted that the combined effect of these loci have been unable to account for a significant proportion of the genetic risk associated with the given disease. This is known as the “missing heritability” problem, and many explanations have been proposed to account for it.⁴³

Popular ideas include the lack of identification of tens, hundreds, or even thousands of genes because they are either rare (minor allele frequencies of less than 1%), have a very small genetic effect (OR of around 1.1 or less), or are not captured by the common arrays employed. Moreover, these rare variants, even if they have large genetic effects (ORs of more than 2.0), still are not detected by the current GWAS arrays, which are based on variants screened by the HapMap Project. As shown by the 1000 Genomes imputation OA GWAS discussed earlier,³⁸ some important variation indeed is missed by these arrays. Depending on the platform and ethnicity, most GWASs will capture only 85% to 96% of the genome and will completely overlook rare variants and copy-number variations. If the first two factors

are considered together, it is apparent that the size of cohorts required to capture these variants is beyond the scope of most investigators. Thus a combined analysis of increasingly large numbers of studies is called for, which necessitates international collaborations to achieve the hundreds of thousands of cases required for detection of such signals.

CONCLUSIONS

The recent rapid improvement in genetic techniques has enabled us to identify a number of genes predisposing to OA. Tremendous efforts have been directed to finding genes that confer risk of both rare and common forms of OA. Although the study of monogenic syndromes that resemble OA or result in early-onset OA has greatly increased our understanding of cartilage biology, it has not helped us understand the molecular genetic etiology of the complex, common form of OA. There are some points in common between. The common complex form of OA seems to be strongly influenced by bone morphogenetic proteins and Wnt signaling, which are central to skeletal development.

On the other hand, genetic studies of OA and other complex diseases have highlighted the need for replication of findings; this would reduce the false-positive signals and points up the need for collaborative efforts. GWASs have revealed a considerable amount of information about the genetic architecture of the disease. OA is a polygenic complex disorder, and many risk alleles, each with a small effect, are important in OA. The GWASs and large candidate studies of OA have so far indicated molecules involved in skeletal development as an etiologic pathway in the late onset of OA as it occurs in the general population. During the coming few years, additional genetic and functional studies will offer a more complete picture of the contribution of genetic factors to OA and the underlying molecular pathways.

Acknowledgments

The authors would like to acknowledge the contributions of Drs. Guangju Zhai and Frances Williams, who were coauthors of this chapter in the previous edition.

Imaging of osteoarthritis

■ CLAIRE Y.J. WENHAM ■ ANDREW J. GRAINGER ■ PHILIP G. CONAGHAN

- Plain radiography is the most feasible method of imaging of osteoarthritis (OA) in clinical practice, although it is often not required because both diagnosis and progression of OA are usually adequately assessed clinically.
- Magnetic resonance imaging visualizes the joint as a whole organ, improving understanding of the pathologic processes, natural history, and potential sources of pain in OA. It is not used routinely for the diagnosis or clinical assessment of OA but is of increasing importance in the research environment.
- Ultrasound allows dynamic assessment of joints; it can assess inflammation (synovial hypertrophy and effusions) and damage (erosions and joint space loss); it also may allow guided therapy for OA joints.
- Other imaging modalities (radionuclide scintigraphy, computerized tomography, positron emission tomography) may be used on a case-by-case basis but do not yet have a routine role in OA investigation or management.

INTRODUCTION

Osteoarthritis (OA) is the most prevalent joint disease worldwide and is increasingly common in aging Western populations. The use of imaging should be considered in light of the particular clinical question and individual tool characteristics. Conventional radiography (CR) is usually not required for the routine clinical diagnosis of OA; because treatment is symptomatic and symptoms are not generally well correlated with the severity of radiographic features of OA, CR does not often assist in treatment decisions unless joint replacement is being considered. It is accepted that the OA disease process involves all tissues of the joint including the cartilage, subchondral bone, synovium, and periarticular tissues, and this has led to the increasing use of modern imaging techniques such as ultrasound (US) and magnetic resonance imaging (MRI) for evaluating the disease, particularly in the research environment.

It should be noted that CR has the longest history in imaging of OA and that there is a predominance of knee studies in the literature for both CR and modern imaging.

CONVENTIONAL RADIOGRAPHY

Plain radiography is inexpensive and widely available, and its images are easily understood. Although, as mentioned, its role in clinical diagnosis and management of OA is limited, it may have a place in excluding other diagnoses at the time of joint pain presentation.

Radiographic image quality is influenced by the sensitivity of the imaging system and the radiographic view. The latter is important because failure to standardize the radioanatomic positioning of the joint between examinations reduces the sensitivity of the technique to detection of changes over time (Fig. 177.1).¹

In OA, subchondral sclerosis and osteophytosis are generally the earliest radiographic features. They increase with time in both extent and size and precede radiographic joint space narrowing (Fig. 177.2), which occurs at a later stage of the disease.¹

What pathologic features can conventional radiography assess in osteoarthritis?

Osteophytes

Osteophytes form as outgrowths at articular margins, capsular insertions, and central articular regions in the unloaded region of joints (Figs. 177.3 and 177.4).

Subchondral bone changes

Increased subchondral cortical plate thickness and subjacent trabecular sclerosis are among the earliest changes in OA. Subchondral bone also demonstrates trabecular loss, which becomes marked with advancing disease (see Fig. 177.2), and increased local bone turnover results in younger, less highly mineralized bone. Radiolucencies noted in the subchondral bone may be juxtaarticular erosions or subchondral cysts, which tend to occur in more advanced OA at sites of increased mechanical load and frequently communicate with the articular surface.

Joint space narrowing

The “interbone” distance was traditionally thought to represent articular cartilage thickness in load-bearing views of the joint. However, it is now recognized from MRI studies that meniscal degeneration and extrusion in the knee joint can contribute to joint space loss.² On CR, joint space narrowing is focal and not uniform, reflecting asymmetric cartilage loss across the articular surface.¹ This feature can prove useful in distinguishing early OA from other arthritides such as rheumatoid arthritis. Marked joint space narrowing is more typical of later stages of the disease (see Figs. 177.1 and 177.2b).¹

Bone remodeling and attrition

Subchondral bone in OA patients is mechanically weaker than that in individuals with nonarthritic joints. It is detected radiographically as flattening and increased congruity between the articular surfaces (Fig. 177.5). With cartilage loss in the load-bearing compartment, tongue-and-groove corrugation may develop, and with complete loss of cartilage the subchondral bone is further flattened (see Fig. 177.5b). Ultimately, the surfaces become deformed, with the collapse of the bone leading to altered limb alignment and deformity.

Radiographic procedures

Validated procedures for the radiographic assessment of OA joints are necessary to standardize assessment of the severity and progression of OA. Standardized radiographic procedures minimize any distortion in the radiographic image of the joint by positioning the joint so that the central ray of the x-ray beam passes between the margins of the joint space (Fig. 177.6). The most reliable and reproducible method for imaging the tibiofemoral compartment of the knee is the standing semiflexed view. Fluoroscopic guidance, which ensures that the center of the x-ray beam is parallel to the tibial plateau, can be used to ensure correct positioning before the radiograph is obtained (Fig. 177.7). The patellofemoral compartment can be assessed using either a lateral or a “skyline” (axial) view (Fig. 177.8). In the axial view the detector is placed on a step and the knee is flexed to 30 degrees from the vertical. The axial view can give a false impression of the patellofemoral alignment if it is undertaken without weight bearing.

Hip radiographs are conventionally taken with the hip in 15 to 20 degrees of internal rotation. Unlike in knee examination there is no advantage to obtaining the radiograph with the patient in a standing position. A lateral oblique view may be used to detect anterior or posterior joint space loss.

The optimal view for imaging the hand is a dorsopalmar view with the fingers in line with the forearm when laid flat on the x-ray detector holder.

Radiographic grading systems

The Kellgren-Lawrence (KL) grading system remains the most widely used scale to quantify radiographic OA lesions. The KL system grades radiographic findings on a scale of 0 to 4 by assessing the presence and severity of osteophytes, joint space width, subchondral bone sclerosis, and deformity of bone contour. It has limitations based on the incorrect assumption that radiographic changes are linear over the course of the disease and that the relationship among these features is constant. In contrast, the Osteoarthritis

Research Society International (OARSI) atlas classification grades tibiofemoral joint space narrowing and osteophytes separately in each compartment of the knee.³

Scoring systems for OA of the hand include the semiquantitative Kallman scale, the Verbruggen numerical scoring system, and a global scoring system in which 32 joints in the hands are scored yes/no for features of radiographic OA. These scoring methods have been demonstrated to have similar reliability and may be used to detect radiologic change in hand OA over time.⁴

Researchers generally agree that weight-bearing views, particularly semiflexed views, are best for evaluating structural progression in the knee with OA, because supine views may not demonstrate joint space narrowing evident on weight-bearing views. Precision of measurement of joint space width (JSW) is improved with radioanatomic alignment of the medial tibial plateau.⁵

A recent OARSI Task Force concluded that measurement of JSW is still a recommended option for structure modification trials, with the understanding that JSW in the knee represents a complex construct and that a long trial duration may be needed.⁶

Fig. 177.1 Differences in joint position at radiography affect joint space assessment. With the knee extended (top row), radiography does not reveal joint space narrowing, but in the semiflexed position (bottom row) joint space narrowing is detected. With advanced disease, lateral radiographs in the standing extended knee view (a) show the femoral condyle resting on the anterior rim of the tibia, producing a gap visible as a joint space in the anteroposterior view (b). Conversely, in the semiflexed view of the same knee, the femoral condyle occupies the central region of the tibial plateau (c) with no cartilage present. No joint space is visible in the anteroposterior view (d).

Fig. 177.2 Radiographic progression of osteoarthritis. Part of macroradiographs (reduced) showing the medial compartment in osteoarthritic knees. (a) Early disease: joint space width greater than 3 mm. (b) Definite disease: joint space width less than 3 mm. With progressive joint space loss, note the increase in subchondral cortical plate thickness and subjacent horizontal trabeculae, which results in a ladderlike appearance that is enhanced by subarticular osteoporosis. Periarticular osteopenia in (a) adjacent to the developing marginal osteophyte is not visible in (b), because osteophytic growth appears to have halted. Osteophytes at the tibial spines appear as irregular outgrowths in (a) and (b). A marginal osteophyte is visible at the posterior rim of the tibia in (b).

Fig. 177.3 (a) Pathologic changes in osteoarthritis and the corresponding characteristic radiographic features visualized in plain radiographs of joints with early- and late-stage disease. (b) Radiograph of a healthy knee. (c) Radiograph of a knee with late disease showing most of the features listed in (a).

Fig. 177.4 Radiographic changes in osteoarthritis (OA). (a) Hypertrophic OA of the hip, with concentric joint space narrowing and extensive osteophytosis and subchondral sclerosis characteristic of the marked bony reaction. (b) Atrophic or destructive OA of the hip, in which there is destruction of subchondral bone, with a relative paucity of osteophyte formation associated with joint space narrowing. (c) Secondary OA of the hip, here caused by a dysplastic hip. The shallow acetabulum and uncovering of the head of the femur results in OA of the upper pole of the joint, with joint space narrowing, subchondral sclerosis, cysts, and osteophytosis. (d) Erosive OA at a distal interphalangeal joint: apart from joint space narrowing, subchondral sclerosis, and osteophytosis, there is loss of the cortical margin, central erosions, and marked soft tissue swelling.

Fig. 177.5 Articular bone distortion and flattening in osteoarthritis (OA), caused by weaker bone. (a) OA knee in the standing extended view showing marked subchondral sclerosis with tongue-and-groove corrugations on the femoral and tibial articular surfaces of the medial compartment. (b) The same knee 21 months later. The corrugations visible in (a) are reduced or absent, which results in a flattened articular surface.

PLANE FOR MEASUREMENT OF MINIMUM JOINT WIDTH

Fig. 177.6 (a) For measurement of minimum joint space width in the tibiofemoral compartment, the plane is taken in the middle of the joint, coincident with load transmission (arrows), perpendicular to the central ray (C) of the x-ray beam and parallel to the film. (b) Arrowheads identify the corresponding site in the anteroposterior radiograph of an osteoarthritic knee. F, femur; T, tibia; F' and T', their projections onto the x-ray film.

JSW can be measured manually using calipers or a graduated ruler and a micrometric eyepiece, or with semiautomated computer software, which has been developed to improve the accuracy of JSW measurement over manual methods. JSW measurements include minimum JSW, mean JSW, joint space area, and JSW at fixed locations.⁹ Software analysis of digital knee radiographs has been shown to be comparable to cartilage morphometry analysis using MRI in detection of OA progression.⁷

Relation to clinical features

There is some discordance among radiographic change, clinical symptoms, and the degree of disability experienced by patients; however, a recent large study noted a strong association between increasing KL grade and increasing frequency and severity of knee pain.⁸ In a study of more than 700 patients with knee pain, the presence of radiographic OA, as defined by the KL score, was consistently associated with the severity of pain, stiffness, and physical function.⁹ However, other studies suggest that only around half of those with radiographic knee OA report knee pain.¹⁰

Likewise, not all patients with knee pain demonstrate radiographic OA. A literature review reported that the proportion of patients with knee pain found to have radiographic OA ranged from 15% to 76%.¹⁰ This lack of consistency across the data might be due to the failure of studies to use x-ray views of all three compartments of the knee, but even when a range of radiographic views is employed, the highest proportion of people with pain who have radiographic knee OA is 76%.¹¹ Earlier radiographic studies of OA, which excluded the patellofemoral joint, may have underestimated the contribution of structural pathologic changes to pain and disability. Duncan and colleagues¹² demonstrated that a posteroanterior view alone identifies around half of the cases of radiographic OA in patients with knee pain; the proportion increased to 87% with two views and 98% with all three views (posteroanterior, supine skyline, and supine lateral).

With regard to individual radiographic pathologic features, the presence of joint space narrowing, and to a lesser extent osteophytes, has been shown to be associated with knee pain.⁸ Joint space narrowing and the presence of osteophytes have also recently been found to be associated with pain in individual hand joints.¹³

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) offers outstanding soft tissue contrast in a tomographic presentation. It provides sections in any plane prescribed by the operator. The technique allows visualization of articular cartilage, fibrocartilage (such as the menisci), synovium, bone contours, bone marrow, and ligaments. Because it is now clear that OA is a disease of the whole joint, MRI has become invaluable, allowing better analysis of both the structure-pain relationship and structural progression. MRI is able to detect pathologic changes at a much earlier stage of the disease than CR, commonly when radiographic findings are normal. An increasing number of studies are documenting the frequency of occurrence of multiple structural

Fig. 177.7 Reproducible radiographic methods for reliable evaluation in knee osteoarthritis (OA). (a) The patient stands in the semiflexed position; both knees are bent and in contact with the film cassette, and the feet are slightly externally rotated (about 15 degrees). The first metatarsophalangeal joint of each foot (arrow) is positioned immediately below and in line with the front edge of the film cassette. The x-ray beam is directed midway between the knees, and the tube's positioning light is aligned with the horizontal plane of the joint. (b) The knee can also be positioned reproducibly in the semiflexed view by using fluoroscopy to position the tibial plateau horizontally and parallel to the x-ray beam. A metallic reference ball is used to correct for radiographic magnification.

Fig. 177.8 Axial or skyline method for imaging the patellofemoral joint. The film is placed on a step and the knee is flexed to 30 degrees from the vertical. This view provides a reliable assessment of the interbone distances at the medial and lateral compartments.

Fig. 177.9 Sagittal T2-weighted fat-suppressed magnetic resonance images of the knee. (a) Bone marrow lesions (BMLs) with an edematous pattern (arrow) are apparent on the anterior lateral trochlea. (b) Image taken 6 months later shows that these lesions have become cystic in nature (arrows). Note also articular cartilage loss overlying the BMLs.

abnormalities in OA joints. In general, MRI abnormalities are seen more frequently with increasing KL grade.

What pathologic features can magnetic resonance imaging assess in osteoarthritis?

Subchondral bone marrow changes

The most common MRI-detected subchondral bone abnormality is manifested as a high-signal area seen on fat-suppressed T2-weighted or short tau inversion recovery (STIR) sequences and has been referred to as a *bone marrow lesion* (BML). The presence of these bone marrow lesions has been associated with both pain and structural progression in the OA knee.^{14,15} Cysts are also observed in the subchondral bone and may be seen to develop with time on a background of a bone marrow lesion (Fig. 177.9).

Bone attrition

Bone attrition is thought to represent remodeling of the subchondral bone and is represented by a flattening or depression of the articular bone cortex. It is commonly seen in conjunction with BMLs. Typically seen in advanced OA, it might occur in milder OA and earlier in the disease than previously thought.¹⁶

Osteophytes

Although marginal osteophytes might be visualized better with CR than with MRI, central osteophytes are more easily detected with MRI. MRI has

Fig. 177.10 Coronal magnetic resonance image of a distal phalangeal joint demonstrating synovitis (after gadolinium contrast administration).

also demonstrated that osteophytes are common in people with no knee symptoms even in the absence of CR changes.

Erosion

Although classically considered a feature of the inflammatory arthritides, bone erosion may be demonstrated in OA. An erosive form of hand OA is recognized on CR, but MRI evidence suggests that erosions may be present even in the absence of CR evidence of erosion,¹⁷ with MRI detecting approximately twice as many joints with erosions compared with CR.¹⁸

Synovitis and joint effusion

Contrast-enhanced MRI remains the gold standard for assessing synovial hypertrophy, with studies demonstrating that the prevalence of definite synovitis in the OA knee in large cohorts is 80% to 90%.^{19,20} Studies of hand OA using contrast-enhanced MRI noted synovitis in over half of the distal interphalangeal and proximal interphalangeal joints (Fig. 177.10).²¹ Joint effusion is best detected on fat-suppressed proton density-weighted or T2-weighted fast-spin echo sequences.

Quantitative MRI markers of synovitis include synovial membrane thickness, synovial fluid volume, and the rate of synovial enhancement after intravenous injection of contrast agent (Fig. 177.11). Accurate quantification of synovitis can be achieved without using contrast agents,²² and recent concerns over the potential toxicity of gadolinium-based contrast agents in patients with severe renal impairment means that this method may warrant further development.

Fibrocartilage and ligament abnormalities

Meniscal tears and extrusion are common in OA (Fig. 177.12). The frequency of MRI-detected meniscal tears increases as the KL grade increases and meniscal damage has also been associated with the development or enlargement of BMLs over time.²³ Fibrocartilage in other joints such as the labrum of the hip and shoulder and the triangular fibrocartilage of the wrist may also show degeneration and tearing, which can be detected with MRI.

Studies have suggested that ligament abnormalities seen on MRI may be an early feature of the disease, and this has been shown in both the knee and small joints of the hand.²⁴ The association of anterior cruciate ligament (ACL) tears and subsequent development and progression of radiographic OA is well described. A high incidence of ACL changes is seen in MRI studies of OA patients, with the occurrence of complete ACL tear reported in up to 20% of one cohort.²⁵

Fig. 177.11 Axial T1-weighted fat-suppressed magnetic resonance image of the knee with gadolinium contrast. The high-signal synovitis is well demonstrated in the suprapatellar pouch and intercondylar notch (asterisks). Osteophytes are also seen (arrows).

Fig. 177.12 Coronal T2-weighted fat-suppressed magnetic resonance image of the knee demonstrating bone marrow lesion and cartilage loss on both sides of the medial joint. The medial meniscus is markedly degenerate with maceration and abnormally increased signal (straight arrow) compared with the normal lateral meniscus (curved arrow). Abnormally increased signal is also seen on both sides of the medial collateral ligament (arrowheads).

Cartilage abnormalities

With the increasing sophistication of MRI sequences available and improved spatial resolution of modern scanners, MRI can demonstrate changes in the morphology of articular cartilage previously impossible to show noninvasively (Figs. 177.13 and 177.14).

In addition, modern techniques have allowed the examination of cartilage quality. A range of techniques such as delayed gadolinium-enhanced MRI of cartilage (dGEMRIC) and T₂ and T₁ρ mapping can provide information on the composition and structure of the cartilage matrix, although these remain research tools and are often difficult to standardize (Fig. 177.15).^{26,27}

Relation to clinical features

A growing number of publications have explored the structural associations of MRI abnormalities with clinical aspects of OA. It is now clear that the

Fig. 177.13 Axial T2-weighted fat-suppressed magnetic resonance image of the knee demonstrating cartilage loss over the crista and medial facet of the patella (arrowhead).

Fig. 177.14 Coronal oblique T1-weighted fat-suppressed magnetic resonance arthrogram of the shoulder with intraarticular gadolinium demonstrating a large osteophyte (black arrow) and areas of cartilage damage to both the glenoid and humeral head (white arrows).

pain in OA is associated with subchondral BMLs²⁴ and the presence of synovitis and effusion,^{19,28,29} with extensive synovitis being strongly associated with knee pain.¹⁹ Furthermore, fluctuations in BMLs or synovitis over time have been associated with change in symptoms.^{15,28-30} The presence of bone attrition and areas of denuded bone have also been associated with knee pain.^{31,32} MRI studies to investigate the association of pain with the presence of osteophytes and meniscal tears have yielded conflicting results, but studies of ACL tears in OA have shown no association with pain.³³ It is also worth noting that MRI will demonstrate abnormalities in the tibiofemoral joint, particularly osteophytes and cartilage defects, in most middle-aged and elderly people even in the presence of normal radiographic findings, regardless of symptoms.³⁴ In hand OA, MRI-detected synovitis, bone attrition, and joint erosion have recently been demonstrated to be associated with joint tenderness.²¹

Fig. 177.15 T2-mapped magnetic resonance image of the knee demonstrating early intrasubstance degeneration of the patellar cartilage seen as prolonged T2 signal (arrow).

Quantification of magnetic resonance imaging pathologic changes

To evaluate cartilage loss in longitudinal studies, sophisticated techniques have been developed to measure cartilage, including measurements of volume and sensitive measures of cartilage thickness.³⁵ An ordered-values approach to describing change in cartilage thickness over time may improve the detection of cartilage loss in longitudinal studies of treatment with potential disease-modifying drugs.³⁶ A subset of core measures that comprehensively describes cartilage morphology and its longitudinal change has been described.³⁷

There are no well-validated quantitative measures for assessing noncartilage features; however, a number of semiquantitative scores have been designed for evaluating knee MRI—for example, the Boston Leeds Osteoarthritis Knee Score (BLOKS), the Whole-Organ MRI Score (WORMS), and the Knee Osteoarthritis Scoring System (KOSS).^{38,39} Each of these measurement tools divides the knee into various anatomical subregions and uses categorical scales to describe the extent of a number of multiple pathologic features within these subregions. The reliability of these methods is often reported, and validity has been reported for the BLOKS BML score. The BLOKS score has recently been iteratively updated to the MRI Osteoarthritis Knee Score (MOAKS), which refined the scoring of BMLs, cartilage, and meniscal pathology. This scoring system demonstrated good reliability, but data are still limited as to its validity and responsiveness.⁴⁰ Semiquantitative systems specifically for scoring synovitis, which have been validated against the more time-consuming gold standard of synovial volumetric analysis, have also been described.^{41,42}

An MRI scoring system for hand OA has been developed—the Oslo Hand Osteoarthritis MRI (OHOA-MRI) score.⁴³ Early data suggest that this may be a useful scoring system (although the metacarpophalangeal [MCP] and carpometacarpal joints are not included) and good reliability was demonstrated; further development of this system is ongoing through the Outcome Measures in Rheumatology Clinical Trials MRI group.

Clinical use of magnetic resonance imaging

At present, given the absence of structure-modifying therapies, MRI has little use in the routine clinical management of OA. MRI studies are complex and there is a range of variables including magnet strength, different acquisition sequences, and use or nonuse of contrast agent. Quantification of MRI findings is improving, and most of the improvements are related to improved accuracy and reliability in measurement of cartilage volume and thickness. Until recently, there has been no agreed MRI definition of OA, but a recent publication in this field provides the first attempt to suggest an MRI definition of tibiofemoral OA.⁴⁴ As a result of this exercise, it has been suggested that MRI OA of the knee can be defined as the presence of both full-thickness cartilage loss and definite osteophyte formation. Alternatively, either full-thickness cartilage loss or definite osteophyte formation, along with the presence of two or more of the features of partial-thickness cartilage loss, meniscal damage or extrusion, BML, or bone attrition, also can define MRI OA of the knee. The usefulness of this proposed definition is yet to be

determined, but it may enable studies of “early” OA before radiographic changes are evident.

ULTRASOUND

Ultrasound (US) is a real-time imaging modality that allows dynamic assessment of joints and provides a dimensional aspect that is not achieved with plain radiography. It is a noninvasive, widely available, and cost-effective technique, minimizing discomfort and inconvenience to the patient, and involves no radiation, which makes repeated evaluation of peripheral joints more feasible. Most work assessing the validity of US has focused on inflammatory arthritis. US has been shown to be more accurate than radiography at detecting cortical erosions in inflammatory arthritis.⁴⁵ Recent work in hand OA has demonstrated that US detected more osteophytosis (especially at the MCP joints) and joint space narrowing than CR⁴⁶ and is a reliable tool for detecting cartilage abnormalities in the MCP joints,⁴⁷ which suggests that US is a useful tool for hand OA research. Other recent work suggests that US is a valid and reliable method for assessing hand OA compared with contrast-enhanced MRI.⁴⁸

What pathologic features can ultrasound assess in osteoarthritis?

US can demonstrate a wide spectrum of structures including the bony cortex, tendons, ligaments, bursae, and peripheral aspect of the menisci. Although articular cartilage can be identified, US is handicapped by its inability to “see” through bone structures. The hardest area of cartilage to examine is that in the central load-bearing regions of a joint where the cartilage is particularly affected in the OA process. US can detect early bone changes in OA as a hyperechoic signal in the area of the attachment of the joint capsule to the bony cartilaginous margin. This corresponds with the eventual appearance of osteophytes seen on the conventional radiograph.⁴⁹ However, pathologic changes deep to the cortex such as subchondral bone changes (e.g., BMLs) cannot be visualized. US readily demonstrates joint effusion and synovitis, although this is easier in some joints than in others (Figs. 177.16 and 177.17). US has been used to assess hand OA, with studies largely in people with erosive OA; effusions and gray-scale synovitis were noted in up to half of the distal interphalangeal and proximal interphalangeal joints assessed.^{50,51} Synovitis and effusion were particularly prevalent in those with erosive OA rather than nonerosive OA.⁵²

Fig. 177.16 Sonogram of the knee joint (taken longitudinally through the suprapatellar pouch). The anterior cortex of the femur is shown (black arrowheads). A knee joint effusion (Eff) and synovitis are apparent in the suprapatellar pouch (white arrows).

Relation to clinical features

Synovitis and effusion, or both, are commonly detected in patients with OA, with between 47% and 100% of patients having synovitis/effusion on US examination of a symptomatic knee.⁵³ US is more sensitive than clinical examination at detecting synovial hypertrophy and effusions, and US detection of gray-scale synovitis has been validated against arthroscopic biopsy results and MRI detection of synovitis in large-joint OA.

In general, there are more US-detected pathologic findings in symptomatic OA than in asymptomatic or control joints. Recent work has demonstrated that painful hand joints are more likely to demonstrate US pathologic changes than nonpainful joints; in particular, synovitis using gray-scale and power Doppler imaging, osteophytes, and joint space narrowing have been demonstrated.⁵⁴ The association between synovitis/effusion and hand pain has been demonstrated in other work.⁵⁰ Although the association between US-detected pathologic changes and symptoms is generally weak, US-detected synovitis or joint effusion has been shown to correlate with painful knee OA. Furthermore, US-detected effusion at baseline has been found to be a significant predictor of total joint replacement at 3 years.⁵⁵

Clinical use of ultrasound

US is highly operator dependent, and adequate training is required. Standard diagnostic criteria are evolving, and semiquantitative scoring techniques have been proposed for the assessment of US findings in hip, knee, and hand OA.⁵⁶ The current roles of US in OA may be acting as a tool for guiding intraarticular injections, helping to differentiate OA from inflammatory diseases, and confirming the presence of osteophytes to support a diagnosis of OA. Work validating US findings as a biomarker for OA is currently ongoing.

OTHER IMAGING TECHNIQUES

Scintigraphy

Bone scintigraphy is an imaging modality that reflects alterations in the metabolic activity of bone through the use of radiopharmaceutical agents, commonly technetium-99m-labeled methylene diphosphonate (MDP). This compound accumulates rapidly in bone by adsorption to the mineral phase of bone. Imaging with a gamma camera detects areas of isotope accumulation representing points of high skeletal bone turnover.

Early studies using scintigraphy in nodal hand OA demonstrated increased activity in the subchondral bone before any typical radiographic changes were seen in OA. A later study involving patients with chronic knee pain compared scintigraphy findings with MRI findings and demonstrated good correlation between MRI-detected subchondral bone lesions and isotope uptake.⁵⁷ Scintigraphy (through detection of these BMLs seen on

Fig. 177.17 Sonogram taken longitudinally across the anterior ankle joint. There is severe synovitis filling the anterior joint space (arrowheads). Tal, talus; Tib, tibia.

MRI) has predicted disease progression in OA. Normal bone scan findings at baseline in individuals with established OA was highly predictive of a lack of radiographic disease progression (as determined by measurement of joint space width) at 5 years.⁵⁸

Scintigraphy is inexpensive and readily clinically available; however, despite the sensitivity of the technique, it shows low specificity and is associated with a significant radiation dose. For these reasons it has limited clinical applicability in OA.

Positron emission tomography

Positron emission tomography (PET) demonstrates metabolic changes in target tissues and reflects glucose metabolism in different tissues. The role of PET in assessing OA is not yet established, and limitations include its cost and exposure to ionizing radiation.

Computed tomography and computed tomographic arthrography

Computed tomography (CT) is a cross-sectional digital imaging method based on advanced radiographic technology. It is particularly effective at depicting cortical bone and may be useful when detailed presurgical

planning is required. CT has an established role in assessing facet joint OA of the spine. CT arthrography, using a contrast medium, has the ability to clearly image the articular surface of a joint, and this technique is comparable to MRI for qualitative assessment of knee cartilage. This may be particularly useful when MRI is unavailable or contraindicated. The technique gives no information on the intrinsic structure of the cartilage and can demonstrate only defects extending to the superficial surface of the cartilage. CT does not yet have an established role in OA trials or clinical practice and has the drawbacks of low soft tissue contrast and radiation exposure.

SUMMARY

Radiography is still a useful imaging investigation for evaluating an individual with suspected OA because of its low cost and availability, and the ease of interpreting the results. The ability of MRI to evaluate the knee as a whole organ and to assess cartilage composition has made it invaluable, both for understanding the natural history of the disease and for guiding future treatments. US can play an important role in diagnosing OA and in monitoring synovitis and response to treatment. The other modalities discussed may be used on a case-by-case basis but do not have a routine role in OA investigation or management.

Assessment of the patient with osteoarthritis and measurement of outcomes

■ JACQUELINE HOCHMAN ■ AILEEN M. DAVIS ■ GILLIAN A. HAWKER

- In clinical practice, the need to perform quantitative assessments is driven by requirements to describe current clinical status, detect change in clinical status, and quantify response to treatment and symptom state attainment.
- Establishment of current clinical status is important, particularly when assessing new patients or those not seen for some time. It provides a quantification of an individual's disease burden and serves to describe the consequence of the disease.
- Detection of change in status provides evidence for worsening or improvement over time.
- Quantification of response to therapy facilitates decision-making as to whether the therapeutic objective has been achieved and whether further intervention is required.
- Quantification of the symptom state attained with therapy facilitates decision-making as to whether the therapeutic objective has been achieved, whether the patient has reached an acceptable level of symptom severity, and whether further intervention is required.

INTRODUCTION

Osteoarthritis (OA) can be considered an illness—that is, the clinical manifestations of a disease for which people seek care—and a disease—that is, the structural changes at the joint level that are associated with OA. The focus of this chapter is the assessment of the “illness” of OA; specifically, the assessment of clinical severity and the consequences of OA from the patient's perspective are discussed.

To address this topic appropriately, the chapter adopts a biopsychosocial model, which focuses on health as an interaction of individual, social, and environmental factors, rather than a biomedical perspective of OA, which views disease as a malfunction of the physical body or somatic pathologic process and includes the presence of the related somatic signs and symptoms. For example, when a strictly biomedical model is used, OA pain is viewed as resulting from a nociceptive transmission arising from the inflamed or damaged joint and surrounding soft tissues.¹ However, use of such a model makes it difficult to explain a number of clinical observations in OA, such as why people with similar OA severity as determined radiographically may experience very different levels of pain or other symptoms.² This imperfect correlation between disease and illness in OA is largely due to the well-documented influence on OA symptoms of not only biologic and physiologic factors but also social, cultural, and personal factors as well as individual subjectivity.³ For example, a large body of work has shown that more supportive relationships are associated with positive psychological and physical health and that the reverse is also true.^{4,5} The impact of social support on health may be direct, for example, by affecting self-esteem or health behaviors (e.g., adherence to therapy), and/or indirect (i.e., a buffering effect or reduction of stress, which positively affects health).⁶ Consistent with this thinking, better coping in OA has been linked to reduced pain and fewer symptoms of depression and anxiety,⁷ and greater self-efficacy has been shown to predict higher thresholds for and tolerance of pain.⁸ Altogether, studies performed to date in OA suggest a relationship between OA pain and mood that is mediated by factors such as self-efficacy and coping

strategies, and modified by social support, age, and gender. Using such a biopsychosocial perspective implies that the assessment of the patient with OA, whether in clinical practice or in clinical research, should ideally incorporate the evaluation of all these factors.

DIFFERENCES BETWEEN PATIENT ASSESSMENT IN CLINICAL RESEARCH AND IN ROUTINE CLINICAL PRACTICE

The requirements for assessments of health status in clinical research are similar to those in clinical practice. In both environments, health status measures are required to be ethical and their scores valid, reliable, and responsive, as is described in more detail in Chapter 2. There are, however, several important differences, the most important being that in routine clinical care the focus is on individual patients, rather than on groups of patients. This focus on the individual requires higher standards of reliability to ensure that measurement error is minimized so that clinicians can be confident in the estimates of health status measure scores and, consequently, in their ability to quantify change in status. In contrast, clinical research most often focuses on groups. For the remainder of this chapter, the focus is on evaluation of individuals with OA in the context of clinical research.

THE WORLD HEALTH ORGANIZATION'S INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH

The use of a conceptual framework to guide one's selection of measures is increasing. The International Classification of Functioning, Disability, and Health (ICF),⁹ developed by the World Health Organization, is a conceptual model that has been widely adopted in rheumatology. The ICF model espouses a biopsychosocial perspective; it proposes complex interactions between *biologic impairments* (loss or abnormality in body structure or physiologic function, including mental functions, e.g., joint pain, fatigue, and mood in OA), *activity limitations* (difficulties an individual may have in executing activities, e.g., walking in OA), *participation restriction* (problems an individual may experience in carrying out valued activities, e.g., travel or work), and *key contextual factors*, both personal (e.g., age, gender, and coping behaviors) and environmental (e.g., use of arthritis health care and social services), which may facilitate or hinder performance across ICF components (Fig. 178.1).

SELECTION OF MEASURES FOR EVALUATION OF PATIENTS WITH OSTEOARTHRITIS

Examination of physical signs of osteoarthritis

The skill, knowledge, and ability to conduct a thorough interview and physical examination are generic requirements in rheumatology (see Chapter 28). Through a combination of verbal, tactile, and visual cues, an impression is gained regarding the nature, severity, and consequence of the condition. Chapter 173 provides a detailed review of the clinical features of OA. As in the clinic, in clinical research the following features should be assessed: bony enlargement, tenderness on palpation, passive crepitus, pain on motion, presence of erythema, and effusion or soft tissue swelling. Joint

Fig. 178.1 Conceptual framework showing complex interactions between biologic impairments, activity limitations, participation restriction, and contextual factors in osteoarthritis (OA).

*Signs and symptoms of disease, both primary and secondary, include joint space narrowing and other structural features of OA, as well as pain, stiffness, fatigue, and other aspects of health, including sleep disruption.

†Activity limitation is referred to as *function or physical disability* in arthritis measures. (From World Health Organization. *International classification of functioning, disability and health*. Geneva: World Health Organization; 2001.)

instability and malalignment, indicating biomechanical abnormality, may also be assessed. However, although the specifics of the examination are unchanged, as noted already, standardization of the assessment is key in the clinical research setting.¹⁰ Training of joint assessors is therefore generally required before study initiation to ensure high agreement within and between assessors on joint findings (i.e., high intrarater and interrater reliability).

The distribution and number of involved joints in OA is often recorded on a joint homunculus, indicating, for example, involvement of the first carpometacarpal joints of the hands, first metatarsophalangeal joints of the feet, hip joints, or knee joints. Pain in the lower back is also often documented. Separate homunculi may be used to indicate tender and/or painful joints versus those that are stiff and/or swollen. This simple descriptive exercise provides a basis for tracking the disorder's evolution—for example, in longitudinal observational studies and in clinical trials in OA—to assess the number of “other painful joints” as a covariate to consider in evaluating response to a therapeutic intervention of an “index” or specifically targeted single painful joint.

Symptom reporting using standardized questionnaires

The selection of specific measures depends on the measurement objective. Measurement may be conducted at the level of an individual joint (e.g., left knee) or anatomic region (e.g., lower extremity or hands), the disease in its entirety (e.g., overall OA), or the person as a whole (e.g., health status or health-related quality of life [HRQOL]). Furthermore, one or more aspects of the condition may be the focus of assessment (e.g., pain, fatigue, and/or function). Therefore a battery of measures, used in combination, may provide a more robust evaluation. The general measures of HRQOL provide an appreciation of an individual's overall condition. However, these measures lack the necessary content and attribution to understand the specific status of the musculoskeletal condition, because health status and HRQOL scores are often influenced by comorbidities. For this reason, it is generally recommended that generic health status or HRQOL measures be used together with disease-specific measures.¹¹

In clinical research, as in practice, the use of standardized questionnaires, ideally completed by the patient, is highly recommended wherever possible. Such patient-reported outcome measures are much less labor intensive to use than those that require administration by an interviewer. The availability of electronic data capture has further facilitated the process of questionnaire completion and data entry when such measures are used, improving data quality in clinical research. Administration of these tools also needs to be standardized for optimal data quality. For example, attention must be paid to standardization of the timing and/or order of questionnaire administration and standardization of physical assessments, because variability may affect the results obtained.

Among people living with OA, pain, stiffness, fatigue, and associated changes in mood (e.g., depression and anxiety) and sleep are key concerns. Recently, increased attention has been paid to better understanding these symptoms in OA with a view to evaluating the adequacy of existing measures and, when needed, developing new measures. This work has identified some limitations to the current tools available to clinicians and researchers to evaluate these symptoms in OA. Many of these tools were not developed specifically for use in this condition but rather as generic measures and/or for use in other clinical conditions. As a result, new OA-specific measures are emerging. Although a detailed review of all measures available to evaluate pain, fatigue, stiffness, sleep, and mood in the context of OA is beyond the scope of this chapter, the most commonly used measures to date in OA clinical research are discussed here. Table 178.1 provides a summary of selected generic, arthritis-specific, and OA-specific measures; Table 178.2 shows the ICF domains that are assessed by commonly used measures. Many of these measures may also be suitable for use in clinical practice.

Assessment of pain

The instruments most often used to date to evaluate pain in OA include both generic pain measures, most notably a visual analogue scale or numeric pain rating scale,¹² the McGill Pain Questionnaire,¹³ and the SF-36 bodily pain scale,¹⁴ and arthritis-specific measures, including the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) pain scale (specific to hip and knee OA)¹⁵ and the Australian-Canadian Hand Osteoarthritis Index (AUSCAN; specific to hand OA).¹⁶ Of the listed arthritis-specific measures, only the WOMAC and AUSCAN indexes, which are both composed of subscales evaluating pain, stiffness, and physical functioning, were developed specifically for use in OA. A number of other pain measures exist but have been less often applied to the OA population.

Recent qualitative research in hip, knee, and hand OA, which has elucidated the key elements of the OA pain experience, has raised concerns about the adequacy of these measures to evaluate pain in OA.¹⁷ Studies have found that the OA pain experience is characterized by the intensity or severity of the pain, the quality or characteristics of the pain (e.g., burning, stabbing, aching), the relation of the pain to activity and thus the impact on functioning and participation, the effect on sleep, and the psychological consequences (e.g., frustration because of the inability to do things that were valued as well as worry about the future).¹⁷ Review of the items and domains of existing pain measures, both generic and OA specific, indicates that most widely used measures do not fully capture the OA pain experience. To address this gap, the Osteoarthritis Research Society International–Outcome Measures in Rheumatology Clinical Trials (OARSI-OMERACT) Measure of Intermittent and Constant Osteoarthritis Pain (ICOAP) has been developed, which evaluates two domains of pain, including intermittent and constant pain, as well as the predictability of intermittent pain using two supplementary questions.¹⁸ It is intended for use alongside a measure of physical disability. The ICOAP has demonstrated reliability, validity, and responsiveness.¹⁷⁻¹⁹

Another recent development is the mounting evidence to suggest that central sensitization may contribute to the pain experience in a subset of people with symptomatic OA.²⁰ Central sensitization in OA may lead to an altered pain phenotype characterized by neuropathic-like symptoms and somatosensory abnormalities.²⁰⁻²² Symptom-based measures including the painDETECT questionnaire have been developed and validated to identify a neuropathic component to pain in other chronic pain populations.²³ A few knee and hip OA studies have employed neuropathic pain symptom measures.^{22,24,25} A knee-specific version of painDETECT, the modified pain-DETECT, has been developed to assess neuropathic-like symptoms in individuals with painful knee OA.²² Preliminary evidence suggests that this measure is valid and reliable; however, validation work is ongoing.²⁶

Assessment of fatigue

Research indicates that fatigue is as common a complaint in OA as in inflammatory arthritis^{27,28} and has a similar negative impact on HRQOL.²⁹ Others have acknowledged the multidimensionality of fatigue in OA—physical,

TABLE 178.1

Selected outcome measures for use in osteoarthritis clinical research

Construct	Generic	Measures to consider

AIMS2, Arthritis Impact Measurement Scales 2; AUSCAN, Australian-Canadian Hand Osteoarthritis Index; Cochin, Cachin hand functional disability scale; DASH, Disabilities of the Arm, Shoulder and Hand questionnaire; FIHOA, Functional Index for Hand Osteoarthritis; HOOS, Hip Disability and Osteoarthritis Outcome Score; KOOS, Knee Injury and Osteoarthritis Outcome Score; ICOAP, Measure of Intermittent and Constant Osteoarthritis Pain; OAKHQOL, Osteoarthritis Knee and Hip Quality of Life; WOMAC, Western Ontario and McMaster Universities Osteoarthritis Index.

emotional, and mental fatigue—and the relationship of OA fatigue to OA pain and pain medications, aging, and poor sleep.²⁸ Currently, no OA-specific fatigue measures exist. The available generic measures of fatigue that might be used to evaluate fatigue in OA clinical research include those that conceptualize fatigue as unidimensional—that is, they provide a single evaluation of overall or “general” fatigue—and those that consider fatigue as multidimensional. The former include the visual analogue scale or numeric rating scale, and two other measures, the Profile of Mood States Fatigue Scale (POMS-Fatigue)³⁰ and the Functional Assessment of Chronic Illness Therapy Fatigue Scale (FACIT-Fatigue),³¹ all of which have been used in the setting of inflammatory arthritis. In comparison, the Multidimensional Fatigue Symptom Inventory (MFSI)³² assesses the many aspects of fatigue that have been identified as important in focus groups of people with OA,^{28,33} including both mental and physical fatigue, and has good psychometric properties. A number of these measures have been used in observational OA research studies, which have found that fatigue measures relate significantly to measures of pain, depression, disability, and sleep.^{28,34}

Assessment of sleep

A number of self-completed measures are now being applied in the OA population to evaluate subjective sleep quality in people with this condition. These include the Pittsburgh Sleep Quality Index (PSQI)³⁵; the Sleep Disorders Questionnaire³⁶; the Chronic Pain Sleep Inventory,³⁷ which has been validated for assessment of sleep disturbances in individuals with chronic pain³⁸; and the use of sleep diaries. Many of these measures incorporate a cut-point score that may be used to discriminate individuals with “poor sleep” or possible underlying sleep disorders from those without. Several of these measures have now been validated for use in hip and knee OA.

Assessment of mood

Depressed and/or anxious mood is common among people living with chronic, painful OA. This has relevance for the assessment and interpretation of scale scores for OA pain and fatigue because both these outcomes

may be strongly influenced by the presence of mood disorders.³⁹ Although a number of measures are available, mood has been most often evaluated in clinical studies of OA using the Center for Epidemiologic Studies Depression Scale (CES-D),⁴⁰ the Beck Depression Inventory,⁴¹ and the widely validated anxiety or depression subscales of the Hospital Anxiety and Depression Scale (HADS).⁴² Of note, the CES-D measures depressive symptoms; age- and sex-adjusted normative values are available, and scores of 16 or higher are considered indicative of significantly depressed mood.

Assessment of activity limitations and participation restrictions in osteoarthritis

Measures of joint tenderness and/or swelling, muscle strength, and joint range of motion provide information about impairment but not about activity limitations or participation restrictions, which are the consequence to the individual of these impairments. Thus these measures generally require supplementation with specific measures of activity limitations and participation restrictions.

Measurement of activity limitations using standardized questionnaires

Standardized questionnaires, many of which are patient self-reported as opposed to interviewer administered, have also been developed to evaluate activity limitations or physical functioning. Although many of these measures have been developed with the idea that the content reflects functioning of a specific joint and hence are considered to be joint-specific measures, the items often reflect activities that involve the entire extremity or functional unit (e.g., walking). Measures that assess activity limitations due to hand OA are different from those used to evaluate hip or knee OA; however, overlap in the content of measures used for OA of joints within an extremity does occur (e.g., hip and knee).

The most commonly used generic measure for hip and knee OA is the physical function subscale of the SF-36.¹⁴ This 10-item measure does include

TABLE 178.2
International Classification of Functioning, Disability, and Health (ICF)
domains assessed by selected outcome measures*

Measure	ICF domain		
	Impairments	Activity limitations	Participation restrictions
Generic measures			
SF-36	Pain Mental health General health Vitality	Physical functioning	Social functioning
Arthritis- and osteoarthritis-specific measures			
WOMAC	Pain++ Stiffness	Pain++ Physical function	
KOOS/HOOS	Symptoms Stiffness Pain† Quality of life++	Pain† Function, daily living Function, sports and recreational activities	Quality of life+
Lequesne Indices	Pain+ Stiffness	ADL knee ADL hip++ Pain++ Walking	ADL hip+
OAKHQOL	Pain/sleep Mental health	Physical activity	Social activities

*Scales within some measures include items that assess more than one ICF domain; where this is the case, + and ++ are used to refer to the distribution of the items; ++ indicates the domain assessed by most items within the scale, whereas + indicates that some items also assess this domain.
†For the HOOS and KOOS, the pain subscale includes approximately equal numbers of items assessing impairments and activity limitations.
ADL, activities of daily living; HOOS, Hip Disability and Osteoarthritis Outcome Score; KOOS, Knee Injury and Osteoarthritis Outcome Score; WOMAC, Western Ontario and McMaster Universities Osteoarthritis Index.

some upper extremity items, however, and represents the physical function of the person more globally. As noted previously, such generic measures should be used in conjunction with disease-specific measures.

Arthritis-specific and so-called joint-specific measures have also been used. For the hip, these include the WOMAC index,¹⁵ the Lequesne Indices of Clinical Severity—Hip,⁴³ and the Hip Disability and Osteoarthritis Outcome Score (HOOS).⁴⁴ For the knee, the WOMAC index, the Lequesne Indices of Clinical Severity—Knee, and the Knee Injury and Osteoarthritis Outcome Score (KOOS)⁴⁵ are most commonly used. The WOMAC physical function subscale includes the same 17 items for the hip and knee and a summated score is created. The measure has been extensively evaluated across the spectrum of severity of hip and knee OA.⁴⁶ However, there has been recognition that the WOMAC index may not include items of sufficient difficulty.⁴⁷ To address this limitation, the HOOS⁴⁴ and KOOS⁴⁵ were developed. These measures include the 17 physical function items of the WOMAC Likert 3.0 (referred to as the *Function, daily living subscale*) as well as a subscale of higher-demand activities, sport and recreational activities (referred to as the *Function, sports and recreational activities subscale*). The HOOS and KOOS scores have demonstrated reliability, validity, and responsiveness.^{44,45} The HOOS and KOOS physical function subscales also are available as short measures and were developed in a population with a spectrum of OA severity.^{44,48,49}

Finally, the Osteoarthritis Knee and Hip Quality of Life (OAKHQOL) instrument has been developed to evaluate HRQOL in individuals with hip and knee OA.⁵⁰ The OAKHQOL tool has demonstrated reliability and validity and has been found to capture the ICF domains better than other measures commonly used to evaluate HRQOL in OA, including the SF-36, WOMAC, and Lequesne instruments.⁵¹

For OA of the upper extremity, generic upper extremity measures, such as the Disabilities of the Arm, Shoulder and Hand (DASH) questionnaire, have been used to evaluate OA-related hand function.^{52,53} The measurement properties of the DASH questionnaire have been evaluated in hand OA,⁵³ and a shorter version, the quick DASH, has also been developed.⁵⁴

Arthritis-specific upper extremity and/or hand measures have also been developed. The Arthritis Impact Measurement Scales (AIMS) have a dexterity subscale that can be used to evaluate one aspect of hand function, but the more specific measures of hand function for OA include the Cochin hand functional disability scale,⁵⁵ the AUSCAN index,¹⁶ and the Functional

Index for Hand Osteoarthritis (FIHOA).^{56,57} The Cochin scale, originally developed for people with rheumatoid arthritis, has been evaluated in people with hand OA and found to be reliable, valid, and responsive.⁵⁵ The AUSCAN index was specifically developed to evaluate hand OA and has been evaluated for reliability, validity, and responsiveness in this condition.¹⁶ The FIHOA evaluates 10 daily activities involving the hands and was developed as a clinical tool for evaluation and symptomatic follow-up of patients with hand OA. This tool has also been evaluated for reliability, validity, and responsiveness.^{56,57} The aforementioned tools represent a sampling of the most frequently used questionnaires for evaluation of physical functioning and activity limitations in hip, knee, and hand OA.

These questionnaires rely on the patient's self-assessment of his or her functional ability or capacity and, as with any measure, scores inherently include sources of measurement error. When someone no longer engages in an activity (e.g., heavy housework), whether due to a disease, lack of necessity, or personal choice, responses to questions may not be an accurate reflection of the degree of impairment. For this reason, performance-based measurement may also be useful.

Performance-based assessment of impairments and activity limitations

Performance-based measures evaluate different components of function than those assessed by patient self-report and may augment the assessment of physical functioning in individuals with OA.⁵⁸ These performance-based measures assess performance of a standardized maneuver, such as walking or rising from a chair, in a controlled setting. Results of such assessments generally correlate only moderately with assessment of similar constructs using self-report measures.⁵⁸ Some work indicates that self-report measures tend to overestimate performance, which suggests a difference between what people perceive they can do and what they actually can do.⁵⁸

For evaluating lower extremity performance, the 50-foot (or other specific distance) walk time, the timed chair stand test, and the timed up and go (TUG) test⁵⁹ are most frequently used in clinical trials and observational studies of hip and knee OA. The timed chair stand test evaluates lower extremity body strength as an indicator of functional status and has been assessed for reliability and validity.⁵⁹ The TUG test assesses basic mobility skills and has been validated for use in hip and knee OA patients awaiting joint replacement surgery. Standardized grip strength and pinch grip measurements, in addition to more comprehensive generic hand function tests, like the Jebsen-Taylor Hand Function Test,⁶⁰ are useful assessments in hand OA. These measurements can be performed reliably by trained assessors.⁵⁹

Assessment of participation restrictions

The impact of arthritis on diverse social roles like relationships with others, occupation, leisure, and community involvement has been identified as a key area of importance in research and practice.⁶¹ However, to date, there has been little evaluation of participation restriction, and assessment of the impact of OA has focused largely on the impact of the disease in terms of impairment and activity restriction (see Table 178.2). The Jette Late-Life Function and Disability Instrument,⁶² which evaluates difficulty with and frequency of participation in a social context (e.g., leisure, social activity, travel, management of health, personal finances), has been used in a study of people undergoing joint replacement for OA.⁶³ Although detailed evaluation of the measurement properties of the tool in OA is lacking, participation was shown to change over the course of the first year of recovery following joint replacement.⁶³ Development and evaluation of measures of participation in people with OA is ongoing.^{64,65}

Evaluation of key contextual factors

As noted earlier, it should be appreciated that a number of contextual factors, including but not limited to the patient's sociodemographic characteristics, education and income, coping style, self-efficacy, social support, and access to and use of health care strategies for arthritis, influence OA impairments, activity limitations, and participation restrictions. Standardized, valid, and reliable measures exist to evaluate these constructs, and depending on the intent of the research, these factors may also warrant evaluation to aid in interpretation of research findings.

RESPONSIVENESS AND INTERPRETATION OF CHANGE IN PATIENT STATUS

Longitudinal assessment of patients, whether in the context of a clinical trial or an observational cohort study, implies the need for measures that can detect meaningful changes in clinical status (i.e., *responsiveness*) as well as

an understanding of what a measured change means for the patient (i.e., *interpretation of the measured change*). Differentiating real change from change occurring within measurement error can also be difficult. It is critical to remember that responsiveness and the interpretation of change, like reliability and validity, are a function of the measure score and context interaction. For this reason, the responsiveness metrics and interpretation for a measure are represented by a range of values based on the varying contexts (e.g., it will differ by the patient sample and type of intervention).

Responsiveness of measure scores

At the group level, responsiveness of a measure is evaluated by an estimate of the effect size. It can be calculated to reflect within-subject change, between-subject change, or both. In the case of paired observations, this effect size is called a *standardized response mean*. The calculation reflects the nature of the paired or unpaired data.

Interpretation of changes in measure scores

There are numerous approaches to interpreting change at the individual level. These include the *minimally clinically important difference* (MCID), threshold methods such as the *patient acceptable symptom state*, and *responder criteria*. The essence of the issue in interpreting change relates to whether measured change reflects *meaningful* change to patients. Thus OA researchers have sought to determine the MCID for various generic and OA-specific measures commonly employed in OA clinical research using a variety of approaches and for different clinical research settings, such as in randomized trials of rehabilitation⁶⁶ and pharmacologic treatments in OA.⁶⁷⁻⁶⁹ The MCID represents the minimum amount of improvement that patients perceive as beneficial.⁷⁰

Both distribution-based and anchor-based methods have been used to establish clinically meaningful change. With a distribution-based method, the effect size may be used to define MCID. However, the U.S. Food and Drug Administration now requires that anchor-based methods be used to determine the MCID when making claims for interventions. Anchor-based methods rely on determining the amount of change in relation to an external indicator of change, usually a patient global rating of how much better or worse he or she is from “slightly” to “a great deal” better or worse.⁷⁰ The MCID is often defined as the mean difference in the change score for patients who rated themselves as “slightly better” after treatment and those who rated themselves as “equal” to their pretreatment level. When this approach

is used, varying MCID definitions for the commonly used OA measures, such as the WOMAC pain and function subscale scores, have been recommended.^{15,71,72}

A threshold approach has also been used to interpret change in OA symptoms and functioning over time. This approach considers that small or large change may occur but that it is not important change if it has not reached a critical threshold value or “state.”⁶⁹ This threshold may be determined by various methods, such as adopting a known population value (e.g., reaching the minimal required physical activity for energy output that has a positive health effect) or a patient-determined value of a “patient-acceptable symptom state,” as has been done in hip and knee OA.^{69,71,72}

Finally, responder criteria have been developed to evaluate meaningful change in pain, function, and patient global assessment using available OA measures. The OMERACT-OARS responder criteria⁷³ have been developed for use in hip and knee OA. Use of these criteria requires that the patient have a certain minimum score before intervention; otherwise, it is impossible for the patient to improve sufficiently to be designated as a “responder,” even if improvement does occur. Comparable criteria for hand OA, including MCID, patient-acceptable symptom state, and responder criteria have not yet been developed.

Changes in patient status over time can be monitored over an extended period using a combination of responder and state attainment criteria. The relationship between responder criteria and state attainment criteria can be best exemplified by the statement, “It is good to be better, but better to be good.”⁶⁹ In addition to the OMERACT-OARS responder criteria, additional responder criteria that have been proposed for OA include minimum perceptible clinical improvement,⁶⁸ minimum clinically important improvement,⁷⁴ and the WOMAC 20-50-70 responder criteria.⁷⁵

CONCLUSION

An essential element in the evaluation of individuals with OA, whether in clinical practice or clinical research, is the need for reliable, valid, and responsive outcome measurement tools. Although many such tools exist for the rheumatologist's use, the sophistication with which these tools are used has increased substantially. This is attributable largely to increased reliance on conceptual models, like the ICF, to inform the selection and interpretation of measures and potentially their interrelationships, and an increased emphasis on identifying and measuring constructs that are important and meaningful to individuals living with OA.

Preclinical osteoarthritis

■ VIRGINIA BYERS KRAUS

- Preclinical osteoarthritis (OA) is the early phase of the disease before abnormalities are apparent on a sensitive imaging modality such as ultrasound or magnetic resonance imaging.
- The strongest evidence for the existence of preclinical OA is provided by the sequence of changes in biomarkers and pathologic stages observed after a major joint injury; this paradigm provides hope that these observations can be translated into diagnostic algorithms for the early detection of idiopathic OA.
- Conventional OA risk factors function poorly for detection of preclinical OA.
- Early diagnosis and intervention in OA would improve the likelihood of disease modification and thereby reduce medical costs, morbidity, and disability.
- Reclassification of the disease as no longer a purely radiographic entity to a disease process that includes preclinical, preradiographic, and radiographic stages would provide a scenario amenable to the development of primary, secondary, and tertiary prevention strategies.

DEFINITION

Preclinical disease is defined as the very earliest phase of a disease process before it becomes clinically recognizable. Alternatively, it is the phase before the appearance of symptoms. For osteoarthritis (OA), clinically recognizable disease has generally been synonymous with the appearance of radiographic changes of OA, including joint space narrowing and osteophyte formation. With the advent of more sensitive imaging techniques, preradiographic stages of disease are recognizable; both magnetic resonance imaging (MRI)¹⁻³ and ultrasound^{4,5} have provided concrete evidence of structural joint abnormalities predating the quintessential radiographic changes associated with OA. These imaging techniques establish a new threshold for what constitutes definitive “clinically recognizable” disease.

It is currently difficult to define preclinical OA as the stage that predates symptoms for two reasons. For one, joint symptoms can be ascribed to multiple causes, and thus symptoms outside the context of the clinically recognizable structural changes of OA cannot currently be definitively diagnosed as being attributable to an OA disease process. Moreover, symptoms of OA wax and wane and might appear and disappear during the preclinical phase of OA, just as they do during the clinically recognizable phases of disease (see Chapter 173 for a discussion of the symptoms of OA). Until our understanding and diagnosis of the cause of early joint symptoms improve, this potentially waxing and waning symptom threshold abrogates our ability to currently define preclinical OA as a presymptomatic stage. Therefore the focus of this chapter is on preclinical OA constituting the early phase of disease before OA-related abnormalities are detectable with MRI or ultrasound (or other sensitive imaging modality) (Fig. 179.1).

Of note, the “preclinical OA” described here should be distinguished from “preclinical models of OA,” which refer to animal models of disease⁶ and are discussed in Chapter 174.

EVIDENCE FOR PRECLINICAL OSTEOARTHRITIS

The World Health Organization defines chronic diseases as being of long duration and generally slow progression (www.who.int/topics/chronic

diseases/en/). Chronic diseases are characterized by complex causality, multiple risk factors, long latency periods, a prolonged course of illness, and functional impairment or disability (www.aihw.gov.au/chronic-diseases/). Many conditions can be considered chronic diseases, including coronary heart disease, chronic obstructive pulmonary disease, and osteoporosis. These chronic diseases are viewed as being amenable to preventive measures; such perception has led to the development of public health strategies to encourage healthy environments and lifestyles. For instance, it has led to efforts to control blood pressure and serum cholesterol levels to reduce the burden of heart disease and stroke. OA fits this chronic disease paradigm well. Such recognition that OA fits this chronic disease paradigm would be expected to broaden the scope of study beyond a focus on diagnosis, monitoring, and treatment of end-stage radiographic disease to include efforts to identify and characterize the preclinical and preradiographic stages to spearhead more effective endeavors to reduce the burden of disease.

The strongest evidence for the existence of preclinical OA is provided by the sequence of pathologic stages observed after a major joint injury. Unlike primary idiopathic OA, posttraumatic OA has a known time of onset, which makes it much more tractable as a method for detecting and monitoring preclinical OA. Based on longitudinal studies, intraarticular pathogenic processes initiated at the time of injury result in radiographic OA 10 to 20 years later.⁷ Longitudinal studies of the aftermath of severe joint injury have convincingly established the existence of a prolonged preclinical molecular phase of the disease characterized by protein and microRNA biomarker abnormalities.⁸⁻¹⁷ After knee injury, cartilage degradation is favored over repair, with increased collagen cleavage taking place.¹⁸⁻²⁰ Within the first month after joint injury in humans, elevations have been documented in the synovial fluid concentrations of cartilage proteoglycan fragments,^{8,20} metalloproteinases (MMP-3/stromelysin-1),^{10,13} tenascin-C,¹⁶ and collagen fragments.²⁰ Aggrecanase cleavage of aggrecan (at 392Glu-393Ala in the interglobular domain) is one of the early key events in arthritis and joint injuries.^{14,15} Elevations of cartilage components in serum can persist over decades after joint injury.⁹⁻¹³ The sustained increased release of cartilage macromolecular fragments after joint trauma is thought to be a harbinger for the development of posttraumatic radiographic OA in patients with injuries. Many of these fragments are not only biomarkers of early disease pathology but could themselves also act to induce and prolong inflammation following joint injury^{16,21} and therefore represent biomarkers within the causal pathway of disease.

In the course of idiopathic (primary) OA devoid of a clear inciting severe acute injury, it is difficult to track the early events. Nevertheless, a few studies have identified premonitory alterations in biomarkers that herald the later appearance of idiopathic radiographic OA. In one study, patients in whom radiographic OA of the hand or knee developed 10 years later had significantly different serum concentrations of four proteins (increased MMP-7, increased interleukin-15, increased plasminogen activator inhibitor-1, and decreased soluble vascular adhesion protein-1) when compared with controls without radiographic OA in the ensuing decade.²² In another study, serum concentrations of the joint tissue components cartilage oligomeric matrix protein (COMP) and hyaluronan (HA) predicted the occurrence, 7 years later, of incident knee joint space narrowing (COMP and HA) and osteophyte formation (COMP).²³ Several studies have suggested that serum COMP predicts the development of radiographic hip OA between 6 and 8 years later.^{24,25} COMP is also increased in the absence of signs of radiographic hip OA in patients with symptoms of hip abnormality.²⁶ These biomarker abnormalities years before idiopathic radiographic OA support the existence of a preclinical phase of OA characterized by serologic abnormalities reflecting preclinical molecular alterations. The existence of preclinical OA is also suggested by the finding of macroscopically

Fig. 179.1 In this schema, osteoarthritis (OA) progresses through stages. Although tools for identifying preclinical OA are limited, events ensuing from acute joint injury attest to the existence of a relatively prolonged asymptomatic preclinical phase of OA before a preradiographic and, later, a radiographic stage. Each of these phases demands a different intervention strategy: the earliest preclinical phase with no apparent illness calls for primary preventive interventions to protect the health of the joint and prevent the appearance of clinically recognizable stages of disease; the preradiographic phase of clinically recognizable but early disease requires secondary preventive measures to halt or slow progress of the disease, if possible, in its earliest stages; the radiographic phase of OA calls for tertiary preventive measures to prevent or reduce the illness of OA, namely the symptoms and disability in the face of a long-term health problem.

degenerated cartilage from cadaveric donors without a clinical history of OA.²⁷ Taken together, these studies demonstrate that metabolic alterations in articular cartilage occur long before radiologic changes are observed and support a chronic disease paradigm for OA that includes a preclinical phase as depicted in [Figure 179.1](#).

DETECTION OF PRECLINICAL OSTEOARTHRITIS

About half the people with knee pain do not have radiographic OA.³ How might those with joint symptoms attributable to preclinical OA be discerned from those with joint symptoms resulting from some other cause? Attempts to identify preclinical OA and subsequent risk for clinically recognizable OA currently rely on a combination of conventional risk factors and the presence of cardinal signs and symptoms of OA. However, baseline conventional risk factors, signs, and symptoms have limited ability to predict subsequent incident radiographic OA 3 to 12 years later.^{28,29} For instance, the use of 10 diagnostic criteria in one study (age, sex, body mass index, previous injury, pain in the entire leg, difficulty descending stairs, palpable effusion, fixed flexion deformity, restricted knee flexion range of motion, and coarse crepitus) was poorly predictive of incident radiographic knee OA 3 years later, with an area under the receiver operating characteristic curve of just 0.59.²⁹ Another long-term (12-year) study that monitored subjects with and without baseline clinical signs and symptoms of OA (crepitus, morning stiffness, knee bone enlargement, and age >38 years) but no baseline radiographic OA suggested an annual development of incident radiographic knee OA of 6.5% in the absence of clinical OA and 7.5% in the presence of clinical OA.²⁸ The limited prognostic ability of conventional risk factors is probably due in part to the fact that the progression from risk factor exposure to the development of radiographic OA depends on the variable likelihood that individuals exposed to the same risk factors will progress through the stages of preclinical OA to preradiographic OA to radiographic OA.

PROGRESSION OF OSTEOARTHRITIS

Because not all radiographic OA progresses to a severe grade of disease or results in joint replacement, by inference, probably not all preclinical or preradiographic OA progresses to more advanced stages of disease ([Fig. 179.2](#)).^{7,28,30} Several hypotheses are encompassed in the graphic in [Figure 179.2](#) in which OA is depicted as a continuum (preclinical to preradiographic to radiographic). One, the rate of progression of OA accelerates with increasing severity of disease. Two, degradation and repair occur simultaneously at all stages of disease (small turning wheels reflecting turnover rates); the greater the degradation rate, the greater the synthetic repair required to meet the demands of the catabolic events (ever larger turnover cycles as the individual progresses further along the trajectory to OA). Third, an excess of catabolism over anabolism drives the trajectory to radiographic OA. Fourth, the mechanisms of progression will probably not be uniform in all

Fig. 179.2 At present, rates of evolution from preclinical to preradiographic to radiographic osteoarthritis (OA) are not precisely known. After a severe acute knee injury, the annual rate of progression in the preclinical phase of OA must be at least 2% to 5% annually to account for the overall average risk for development of radiographic OA of 50% by 10 to 20 years later⁷; under less extreme circumstances the rate is probably lower. Knowledge of rates of progression to radiographic OA from preradiographic OA are limited but may be estimated at 7% to 8% annually given the current information available.²⁸ The rate of progression of radiographic OA to more severe radiographic stages is estimated to be 2% to 19% annually based on calculations using data from the placebo arms of a number of studies (summarized by Manno and colleagues³⁰). These figures should be treated as rough estimates in need of refinement through future longitudinal studies with more comprehensive patient phenotyping of different joints and patient subtypes and sensitive imaging and biochemical markers.

OA phenotypes.³¹ Fifth, the proportion of at-risk individuals who proceed along the OA trajectory at any point in this continuum is uncertain.

Surprisingly little is known about the actual rates of progression through each stage. The rate of progression from preclinical OA to preradiographic OA is entirely unknown. In the specialized circumstance of severe acute joint injury, radiographic OA develops in 50% of individuals after an average of 10 to 20 years⁷; this equates to an estimated rate of progression during the preclinical stages of at least 2.5% to 5% annually. As described earlier, the rate of progression from the preradiographic phase to incident radiographic OA may be estimated from one study to be 6.5% to 7.5% annually in the absence or presence of symptoms.²⁸ The rate of progression from

TABLE 179.1

Summary of studies providing estimates of radiographic progression of osteoarthritis*

Study (N in placebo arm)	Study duration (wk/yr)	Subjects with radiographic progression among those with baseline symptoms N progressors/N with symptoms (% progression; % per year)	Subjects with radiographic progression among all subjects N progressors/N total (% progression; % per year)
Hip studies			
Echodiah (136)	156/3	30/52 (57.7%; 19.2%)	30/136 (22%; 7.3%)
Eradias (127)	156/3	24/46 (52.2%; 17.4%)	24/127 (19%; 6.3%)
Knee studies			
Pavelka (54)	156/3	3/14 (21.4%; 7.1%)	3/54 (6%; 2%)
Reginster (69)	156/3	12/26 (46.2%; 15.4%)	12/69 (17%; 5.7%)
Doxy (120)	120/2.31	16/37 (43.2%; 18.7%)	16/120 (13%; 5.6%)
Gait (50)	104/2	4/30 (13.3%; 6.7%)	4/50 (8%; 4%)
Kostar (625)	104/2	55/316 (17.4%; 8.7%)	55/625 (8.8%; 4.4%)
Stopp (163)	104/2	19/68 (27.9%; 14%)	19/163 (11.7%; 5.8%)

Progression is defined as change in joint space width greater than 0.5 mm by study end.

*Data from placebo-treated subjects.

Data derived from Manna RL, Bingham CO 3rd, Paternotte S, et al. OARSI-OMERACT initiative: defining thresholds for symptomatic severity and structural changes in disease modifying osteoarthritis drug (DMOAD) clinical trials. *Osteoarthritis Cartilage* 2012;20:93-101.

preradiographic to radiographic OA is estimated to be 2% to 19% annually based on calculations using data from the placebo arms of a number of studies summarized by Manno and colleagues³⁰ and shown in Table 179.1; higher rates of progression were observed in subsets of subjects with a high symptom load. Further longitudinal studies are needed to provide more precise estimates of progression for each stage of disease and to understand how these rates may differ by patient subsets, joint type, and risk factors. The paradigm of joint injury in humans would seem to be the best place to start to gain such information.

TRIGGERING MECHANISMS

As proposed for other diseases,³² the action of additional potentiating “triggering” mechanisms in the presence of preclinical disease also influences progression to events or, in the case of OA, progression to preradiographic and radiographic OA. Given the waxing and waning nature of symptoms, there is every reason to think that disease progression undergoes nonlinear or phasic progression; this has been supported by the observation that metabolic disturbances in cartilage turnover, as reflected by serum COMP concentrations, are phasic and elevated during periods of radiographic knee OA progression.³³ Molecular differences between the cartilage at different joint sites,^{34,35} and the generation of specific neopeptides from joint tissues with metabolic disturbances, suggest that biomarkers might be developed in the future that reflect disease activity of specific joint types or even of OA specifically. Taken together, biomarkers indicative of joint tissue metabolism could constitute a means of detecting the preclinical molecular stages of OA in advance of preradiographic OA and assess the impact of specific triggering events.

With the recent recognition of a definite and central role for innate immunity in OA²¹ it is now possible to develop a holistic understanding of the pathogenesis of the disease process. From its inception, OA is an active disease process, not just a process of mechanical attrition, involving mechanical insults that activate mechanosensors to induce cellular responses to altered mechanical load, including the induction and activation of specific matrix degrading enzymes³⁶; this propagates inflammation through the generation of molecular fragments that act as disease associated molecular patterns to activate the innate immune response (Fig. 179.3)—a major biologic transducer of disease progression. The cogwheel graphic in Figure 179.3, which symbolizes the ability of cogs to start and stop, portrays the penchant for OA to wax and wane. This representation shows the interaction of inciting mechanical insults and environmental factors, the potentiation by risk factors and genetics, and the resulting activation of an innate immune response and impaired wound healing³⁷ leading to the chronic disease process that we know as OA. Given this newly emerged understanding of the pathogenesis of OA, it is intriguing to speculate that a robust innate immune response would protect against infectious disease, particularly in the pre-antibiotic era, but be deleterious in potentiating age-related

Fig. 179.3 This model depicts osteoarthritis (OA) as a condition incited by the mechanical insults of microinjury, macroinjury, and environmental factors. The interaction of extrinsic inciting insults with potentiating intrinsic factors determines the relative susceptibility to progression of disease mediated by a biologic innate immune inflammatory response analogous to a chronic wound. The resulting pathology is manifested first as a preclinical (not clinically recognizable) entity, with progression in some individuals to preradiographic stages (detected by sensitive imaging modalities) and eventually to radiographic stages. The interacting cogwheels, able to turn intermittently, depict the penchant for OA activity to wax and wane. The exact timing of the onset of the illness of OA that includes symptoms in this continuum of OA pathogenesis is unclear at present.

chronic diseases in our current postantibiotic era characterized by increasing longevity. There are in fact hints that the latter is true based on studies showing that low innate production of cytokines on *ex vivo* stimulation of blood with lipopolysaccharide is associated with a lower risk for OA and the absence of OA in old age.^{38,39} Conversely, a robust repair response would be expected to protect from OA and prevent OA progression along the stages of disease (see Fig. 179.2). The capacity for joint tissue repair differs by

joint type^{35,40} and is likely a key determinant of OA prevalence and rates of progression. Data suggest a joint type specific gradient of repair responses, with ankle>knee>hip repair capacity that would explain the rarity of severe ankle radiographic OA⁴¹ and the apparent greater rate of progression of hip versus knee OA.³⁰ A better understanding of these differences could enhance our ability to identify at risk joints early in the disease development stage.

TREATMENT PARADIGMS

OA is a slow, insidious, and debilitating process that like other prominent chronic diseases, is probably more amenable to remission early in the disease process. Maintenance of cartilage homeostasis would be expected to halt progression of the disease. A tipping of the homeostatic balance in favor of anabolism over catabolism would be expected to reverse the disease. As noted by Luyten and coauthors,⁴² inactivation of inflammation and joint destruction would be sufficient in some patients at a very early stage of the disease; however, additional therapies targeting tissue restoration through cell proliferation and differentiation might be needed to achieve the ultimate goal of complete recovery of structural joint integrity. The pattern of biomarker alterations observed after joint injury matches the pattern of cartilage components released from cartilage stimulated *in vitro* with proinflammatory cytokines.^{20,43} Many treatments exist for *in vitro* cartilage injury and suggest potential benefit. These biomarker observations provide great hope that disease-modifying therapies are within reach for early pre-clinical OA once it can be diagnosed reliably, because there are already many known pharmacologic agents with chondroprotective effects in the cartilage explant model and acute injury animal models of OA.^{20,44}

POTENTIAL BENEFITS WITH EARLY DIAGNOSIS OF OSTEOARTHRITIS

Annual medical expenditures in the United States attributable to OA are estimated to be as high as \$185.5 billion, or 19% of the aggregate medical

expenditures for the U.S. adult population.^{45,46} It is generally agreed that the prospect for early diagnosis and intervention in OA would improve the likelihood of disease modification and thereby reduce medical costs, morbidity, and disability. In this regard, OA fits the description provided by Machiavelli more than 500 years ago, "In the beginning of the malady it is easy to cure but difficult to detect, but in the course of time, not having been either detected or treated in the beginning, it becomes easy to detect but difficult to cure."⁴⁷ A precedent for improved outcomes with early identification and treatment now exists for rheumatoid arthritis.^{48,49} This paradigm should help facilitate the approach to the diagnosis and treatment of OA.

SUMMARY

It is generally agreed that the early stages of OA would be more amenable to modification, including halting or slowing the disease process to prevent recalcitrant, disabling, and more costly late stages of the disease. Consensus, however, is needed for a new paradigm of OA that conceives of a pathologic continuum beginning with a preclinical stage; such a conception is the norm for other chronic diseases.⁵⁰ This would require reclassification of the disease from a purely radiographic entity to a disease process with a preclinical phase characterized by serologic abnormalities such as elevations of cartilage extracellular matrix components in body fluids, a preradiographic stage, and a radiographic stage. Just as not all radiographic OA progresses, it is likely that not all preclinical or preradiographic OA progress to later stages. To gain this information, more studies are needed to discern and monitor the disease process from its incipient to its end stages. The scenario of acute joint injury, with a known date of onset, provides a potential gateway to understand the preclinical stages of OA and offers the most promising context in which to elucidate the continuum of pathologic stages of this joint disorder. Ultimately, it will be important to establish the temporal relationship between changes in imaging markers and onset of symptoms and the molecular events that predate these manifestations of disease to achieve the goal of ultimately preventing and curing OA.

Assessment of imaging outcomes in osteoarthritis

■ DAVID J. HUNTER

- In the absence of a therapeutic intervention that can irrefutably modify structural progression, the role of monitoring progression of osteoarthritis (OA) in clinical practice is limited.
- Regulatory approval of potential therapies for OA requires that structural alteration be linked to some clinical benefit either at the time when the structure was measured or at a later point in time.
- Progression of knee OA is typically assessed by measuring change in the width of the joint space between the medial femoral condyle and medial tibial plateau on plain radiographs.
- Though yet to be formally accepted by regulatory authorities, magnetic resonance imaging has several advantages in monitoring progression of OA of the knee.

INTRODUCTION

Osteoarthritis (OA) is the clinical and pathologic outcome of a range of disorders that result in structural degradation and functional failure of synovial joints.¹ The joint failure may cause pain and disability and is ranked as the leading cause of disability in elders. Current estimates suggest that OA affects an estimated 21 million Americans² and that symptomatic knee OA develops in 6% of adults older than 30 years³ and in 13% of those older than 60.⁴

Despite this prevalence, OA remains a condition that is poorly understood and for which few safe and effective therapeutic options are available. In an effort to target the disease (both symptoms and structure), modifying structural progression has become a focus of drug development in OA. However, further development of definitive structure-modifying therapies is constrained by a number of factors, including (1) the need for long-term follow-up to observe changes in structure (and potential therapeutic effects on it), (2) the heterogeneous clinical manifestations of OA, and (3) the unclear relationship between structural progression and clinical endpoints. Underpinning the capability of demonstrating structural change in clinical trials is access to responsive and highly reproducible markers that measure the rate of progression in individuals. Once we have an approved disease-modifying agent, we will also need such measures for patients in clinical practice.

Traditionally, measurement of structural change (often incorrectly paraphrased as cartilage loss⁵) in OA has been performed on plain radiographs. Standardized radiographic protocols for measuring joint space width (JSW) in the medial tibiofemoral (TF) compartment have become accepted for quantifying structural progression in knee OA. Newer methods, including magnetic resonance imaging (MRI), a noninvasive three-dimensional method for assessing joint morphology, may eventually supplant the widespread use of plain radiographs in clinical trials.⁶

This chapter focuses on the imaging assessment of OA outcomes. Most of the chapter focuses on the TF compartment of the knee and specifically on radiographic and MRI developments in measuring progression of OA. Interpretation of these measures is considered and directions for future research and development proposed.

ROLE IN RESEARCH VERSUS CLINICAL PRACTICE

In the absence of a therapeutic intervention that can irrefutably modify structural progression, the role of monitoring progression of OA (either by

plain radiography or MRI) in clinical practice is limited. Hence, there is currently no rationale for obtaining serial radiographs if the clinical state remains unchanged. Thus what follows is a description of the principal methodologies used to monitor structure in clinical research. As outlined in Chapter 177, OA radiography does play a role in defining the presence of disease, determining the compartment or compartments of the joint that are affected, and categorizing its severity. In addition, conventional radiography is commonly used in clinical practice because radiographs are easily interpreted.

REGULATORY REQUIREMENTS

Radiographic measurement of joint space narrowing (JSN) is currently recommended in the U.S. Food and Drug Administration⁷ and European Medicines Agency⁸ guidance documents as the imaging endpoint for clinical trials of disease-modifying OA drugs. At present, an alteration in structural progression would probably be determined by plain radiography, but it is possible that newer technologies may include MRI or even ultrasound once appropriately validated. Currently, approval of potential therapies for OA requires that structural alteration be linked to some clinical benefit either at the time when the structure was measured or at a later point in time. With this concept in mind, it is obviously important that improvements in OA structural features be ascertained that are more likely to be linked to the clinical symptoms experienced by patients or, alternatively, that can serve as a surrogate for a clinically meaningful outcome.⁹

PLAIN RADIOGRAPHY

Conventional radiography is the least expensive method for imaging joint structure in patients with OA. The presence and severity of disease are typically classified with the Kellgren and Lawrence (K&L) grading system,¹⁰ a system that is heavily dependent on the osteophyte for classification of disease. Because of the inherent limitations of the K&L grading system, individual grading systems for the different disease features, including osteophytes and JSN, have been developed. These site-specific ordinal scales (graded 0 to 3) categorize the feature according to its severity and are accompanied by published atlases that provide images representing the specific grades.¹¹ Observational studies show a variable relationship between individual radiographic features, pain, and function in OA.^{12,13} Progression on the ordinal JSN scale is a criterion commonly used for assessment of OA progression, and complete loss of joint space characterized by bone-on-bone contact, which corresponds to JSN grade 3, is one of the factors considered in the decision for joint replacement.¹⁴

Radiographic joint space width

Progression of knee OA is typically assessed by measuring change in the width of the space between the medial femoral condyle and medial tibial plateau on plain radiographs.¹⁵ This generates a continuous measure of JSW, and a reduction in this space is termed JSN (not to be confused with the ordinal measure described earlier). From the reduction in this space the health, integrity, and thickness of hyaline articular cartilage are inferred.^{5,15,16}

Radiographic protocols

Radiographs are a two-dimensional projection of a three-dimensional joint structure that are subject to problems caused by variability in joint repositioning. The conventional standing, fully extended anteroposterior protocol

of the knee in the weight-bearing position was the most commonly used technique and continues to be the usual approach for diagnosis. However, this protocol is not recommended for monitoring disease progression because there is no attempt to standardize the degree of knee rotation or flexion or the radiographic beam for optimizing alignment of the medial tibial plateau.¹⁷

Standardized radiographic protocols of the flexed knee for measuring JSW in the medial TF compartment have become accepted for quantifying changes in TF knee OA. Recent analyses suggest that the better the

positioning in terms of medial tibial rim alignment (or inter-rim distance) with the radiograph beam, the greater the sensitivity in detecting OA progression and the more accurate identification of the location of JSN¹⁸ (Fig. 180.1). Long-term reproducibility of knee positioning, as assessed by variability in the inter-rim distance (also termed intermargin difference), or the distance between the anterior and posterior rims of the medial tibial plateau on serial radiographs, was shown to be significantly less satisfactory on medial tibial plateau and fixed-flexion radiographs than on semiflexed anteroposterior and Lyon-Schuss radiographs.^{19,20} There remains, however, considerable controversy over the preferred method of acquiring knee radiographs¹⁵ and measuring JSW.¹⁶

Fig. 180.1 Positioning of the subject for fixed-flexion (FF) and Lyon-Schuss (LS) radiographs and examples of good and poor alignment of the medial tibial plateau (MTP) with the radiographic beam. (a) Positioning of the subject. The FF protocol uses a fixed 10-degree caudal radiographic beam and positions the thighs, patellae, and pelvis flush with the film cassette and coplanar with the tips of the great toes, which results in a fixed knee angulation of approximately 20 degrees of flexion. In the LS protocol, positioning is identical to that for an FF view. However, the angle of the radiographic beam is not fixed but is adjusted for each examination to align the MTP with the radiographic beam. Alignment is achieved with fluoroscopy to superimpose (within 1.5 mm) the anterior and posterior margins of the plateau. (b) Good alignment, as defined by virtual superimposition of the anterior and posterior margins at the center of the plateau (arrow). (c) Radiograph with poor alignment, as depicted by the wide separation (>1.5 mm) of the anterior and posterior margins of the MTP (arrows) or so-called inter-rim distance. (Reproduced with the authors' permission from Merle-Vincent F, Vignon E, Brandt K, et al. Superiority of the Lyon Schuss view over the standing anteroposterior view for detecting joint space narrowing, especially in the lateral tibiofemoral compartment, in early knee osteoarthritis. *Ann Rheum Dis* 2007;66:747-53.)

Methods of measuring joint space width

JSW can be measured either manually with the use of callipers or a simple graduated ruler and a micrometric eyepiece or in a semiautomated fashion with computer software.²¹⁻²³ The most common metric that is generated is the minimum JSW, which constitutes the smallest distance between the medial femoral condyle and medial tibial plateau. The smallest standard deviation of the difference between test-retest measurements of minimum JSW in pairs of radiographs reaches about 0.1 mm in the most reproducible methods,^{23,24} which equates to a smallest detectable difference of at least 0.2 mm, a value that remains relatively large in view of the 0.10- to 0.15-mm expected average annual rate of JSN in knee joints with OA.²⁵ Recent analyses have suggested that measuring JSW at fixed locations along the joint (the JSW[x] coordinate system) is both more reliable and more sensitive to change than the minimum JSW is (Fig. 180.2).²²

MAGNETIC RESONANCE IMAGING

Though yet to be formally accepted by regulatory authorities, MRI has several advantages in monitoring progression of OA of the knee.²⁶ There is a significant body of supporting data on the longitudinal change in cartilage morphology (thickness, volume) as a primary endpoint reflecting OA progression/cartilage loss.²⁷ MRI of the knee can directly visualize articular cartilage and cover the entire joint three-dimensionally in one examination, which means that the cartilage, its defects, and other joint tissue involvement can be visualized directly regardless of their location.²⁸

Methods of analysis of magnetic resonance images

Broadly speaking, the features of OA can be measured semiquantitatively or quantitatively by MRI, and either morphologic or compositional measurements of articular cartilage can be obtained.

Observer-dependent semiquantitative image analysis

Semiquantitative scoring is a valuable method for assessing multiple features of the knee with conventional MRI acquisitions.²⁹⁻³² Such approaches score, in an observer-dependent semiquantitative manner, a variety of features that are currently thought to be relevant to the functional integrity of the knee or potentially involved in the pathophysiology of OA. These articular

Fig. 180.2 (a) Landmarks and definition of the coordinate system.²² (b) Location-specific measurement of joint space width, JSW(x) ($x = 0.2, 0.225, 0.25$, and 0.275), in the medial compartment (minimum JSW). Measurements of JSW(x) are made at the x-locations (vertical line segments) defined by the coordinate system. (Courtesy Dr. Jeff Duryea.)

features can include articular cartilage integrity, subarticular bone marrow lesions (Fig. 180.3), subarticular cysts, subarticular bone attrition, marginal and central osteophytes, anterior and posterior cruciate ligament integrity, medial and lateral collateral ligament integrity, synovitis/effusion (Fig. 180.4), medial and lateral meniscal integrity, intraarticular loose bodies, and periarticular cysts/bursitis. These instruments for scoring OA on MRI have shown adequate reliability, specificity, and sensitivity, but their sensitivity to change is modest.²⁷

Fig. 180.3 Sagittal fat-suppressed intermediate-weighted magnetic resonance image depicting diffuse ill-defined hyperintensities (arrows) abutting the subchondral plate in the weight-bearing lateral view of the tibia and femur that are characteristic of bone marrow lesions. Also apparent are extensive osteophytosis and a cartilage defect in the lateral tibial plateau and femoral condyle and bone attrition in the tibial plateau. An oblique tear of the partially macerated posterior horn of the lateral meniscus (arrowhead) has occurred.

Fig. 180.4 Sagittal fat-suppressed intermediate-weighted magnetic resonance image showing knee joint effusion (arrow) and infrapatellar synovitis (arrowheads). On this non-contrast-enhanced image the magnitude of synovitis is difficult to determine.

Computer-aided image processing to quantitatively assess whole-joint morphology (cartilage, bone, synovium, etc.)

The three-dimensional coverage of an entire cartilaginous region by MRI allows direct quantification of cartilage volume, surface areas, and thickness. Quantitative analysis of cartilage morphometry is becoming widely used for the assessment of OA.²⁸ Measurements of cartilage volume with MRI have previously been shown to correlate well with *ex vivo* assessments of cartilage volume (stripped away from bone).^{33,34} Measurement of cartilage volume or thickness provides quantitative data with which to monitor the progression of OA.³⁵ The ideal segmentation strategy is one that produces accurate and precise results in a reasonable amount of time with minimal subjectivity (Fig. 180.5). These methods are described in more detail elsewhere.²⁸ In addition to cartilage volume, other features such as bone marrow lesion volume and synovial fluid volume can also be quantitatively assessed. Of the MRI measures used to date, measurement of cartilage morphometry is the most mature, with a substantive literature base demonstrating its validity, responsiveness, and reliability.^{27,36}

Compositional measures of articular cartilage

Even though quantitative measurement of morphology can be used to monitor loss of cartilage tissue, there is interest in using MRI to detect changes that precede gross tissue degradation. Applications of parametric mapping techniques sensitive to early cartilage damage, including T2 mapping, dGEMRIC, and T1rho, have been extensively reviewed elsewhere.^{37,38} Intuitively, compositional measures may have a great role to play in examining changes that occur in early disease before gross defects become apparent, whereas morphologic measures—both semiquantitative and quantitative—may have a greater role in later stages of disease. Particularly for the supposedly “early” changes of OA, however, the natural course of these changes and their relationship with clinical outcome remain to be established.

Semiquantitative progression

Some recent studies have used assessment of semiquantitative cartilage morphology on MRI as the outcome for ascertaining important risk factors for disease progression.²⁷ The menisci have many functions in the knee, including equal distribution of stress between the relatively incongruous TF joint surfaces, enhancement of stability, and lubrication. Damage to the morphology of the meniscus and alteration in its position appear to be a potent risk factor for progression of cartilage lesions measured semiquantitatively on MRI.³⁹ Bone marrow lesions have also been found to be associated with semiquantitatively measured compartment-specific progression of OA in cartilage.⁴⁰

Mechanical factors are the dominant risk factor for structural progression, and varus malalignment was shown to predict medial TF progression measured both quantitatively and semiquantitatively after adjusting for other local factors (meniscal damage and extrusion, laxity).⁴¹ Interestingly, quantitative measurement of cartilage in this cohort appeared to demonstrate greater responsiveness than did semiquantitative measurement; however, many of the subjects whose condition progressed had a late stage of disease, for which morphometric measures appear to demonstrate their greatest responsiveness.

Quantitative magnetic resonance imaging-based cartilage measurements for evaluating longitudinal change in cartilage morphometry

More extensive discussion of the technical validity, precision, and sensitivity to change of quantitative measures of cartilage morphology can be found elsewhere.⁴² Early longitudinal studies suggested that changes in cartilage volume or thickness on the order of -4% to -6% (standard deviation of $\approx 5\%$) occur per annum in OA in most knee compartments monitored for periods of up to 3 years.²⁸ The annual changes in cartilage volume/thickness exceeded the precision errors and appeared to be associated with clinical symptoms, as well as with time until total knee arthroplasty.^{28,43} One study detected loss of cartilage volume in the absence of any change in radiographic JSW, thus suggesting that MRI has greater sensitivity to change than radiography does.⁴⁴

More recent studies, however, have observed smaller rates of change than those just quoted, with rates of about -1% to -3% and standardized response means of -0.3 to -0.5 per year.^{45,46} These more conservative estimates have important implications for planning future clinical trials of disease-modifying treatments of OA with MRI techniques.

The conservative study designs based on large MRI progression series currently in the public domain require large sample sizes if quantitative cartilage morphometric measures are used as the endpoint. If one could

Fig. 180.5 (a) Axial (top) and coronal (bottom) images in a patient with knee osteoarthritis and segmentation of cartilage. Note that the total subchondral bone area is segmented, also in areas in which the cartilage has been lost (green line). In this way, not only cartilage volume and thickness but also the denuded area can be computed. (b) Segmented cartilage model. Patellar cartilage is purple, femoral (trochlear) cartilage is turquoise, and the lateral femoral condyle is red. The tibial cartilage displays thickness maps, with the thickest regions in red and the thinnest in blue. (a, Courtesy Institute of Anatomy and Musculoskeletal Research, Paracelsus Medical University, Austria, under the supervision of Felix Eckstein; b, Courtesy Dr. Jan Hohe, PhD, Chondrometrics GmbH, Ainning, Germany.)

confidently design studies based on smaller sample sizes or shorter study durations (or both), this would, however, greatly reduce the resource implications for MRI-based interventional studies. Several studies have suggested that baseline clinical, biomarker, and imaging features are predictive of progression of cartilage loss in the medial compartment of the knee and could be used to provide greater study power by selecting a population at greater risk for more rapid progression.⁴⁷

Issues in interpreting progression of quantitative measures

Some attempt has been made to develop nomenclature for the regions of the knee and the different measures that can be performed (from volume to thickness to denuded area and beyond), but there is probably great redundancy in many of these measures, and the field would benefit from simplifying the terminology and identifying those that are most highly correlated with clinical outcome.⁴⁸

A substantial percentage of the variability in cartilage volume is determined by joint surface area.⁴⁹ Wang and colleagues⁵⁰ demonstrated that the medial and lateral tibial plateau area increased over a 2-year period (2.2% and 1.5% per annum, respectively), with increases at the medial (but not lateral) part of the tibia being larger in men, in participants with a high body mass index, and in subjects with a higher baseline grade of medial JSN. Metaphyseal enlargement with age and OA⁵¹ might create problems for measurements of cartilage volume that do not adjust for bone size, and either adjustment for subchondral bone area or direct measurement of cartilage thickness has thus been recommended.⁴⁹

In early OA, cartilage may not be thin but rather thicker and swollen with water, which is imbibed by cartilage when the collagen network is disrupted and the charge of proteoglycans is altered.⁵² Thus, measuring cartilage volume in regions of the knee (e.g., medial tibia area) and regional mean thickness as distinct from focal measures of change (region-of-interest analysis centered around focal defects⁵³) and measures of denuded cartilage may provide very different results about the important pathologic changes

occurring in early disease. Distinguishing what measures are most discriminatory at each stage of the disease process is essential for using these measures appropriately.

If structural modification is the intent of treatment, it should be done while being mindful of attaining improvement in symptoms and not be divorced from it. This is particularly important because of the current predilection of focusing treatment targets on hyaline articular cartilage. Articular cartilage is both aneural and avascular. Consequently, cartilage is incapable of directly generating pain, inflammation, stiffness, or any of the symptoms that patients with OA typically describe.⁵⁴ Given the relative unimportance of the symptomatic manifestations of OA, it is ironic that articular cartilage has received so much attention whereas other common sources of symptoms in the joint are ignored. We need to pay greater heed to the pivotal role of other tissues in disease symptoms and etiopathogenesis, especially synovium, bone, fat, meniscus, and ligaments.

CONCLUSION

OA is the most common form of arthritis and one of the leading causes of disability in elders. With little currently available for the treatment of this disease, better understanding of responsive and valid structural endpoints is essential for identifying potential new interventions for treating this disease. The measures of progression that we are currently using are optimal for late stages of disease and not early disease, for which intervention may be more rational. Currently, a large number of epidemiologic and clinical trials of OA are under way and are collecting both plain radiographic and MRI data. Investigations to identify the most valid and responsive set of endpoints are ongoing in these studies. Before recommending the widespread use of one particular imaging construct in structure-modifying clinical trials it is essential that we have this information, as well as an established relationship with clinical endpoints such as pain, function, and need for joint replacement.

Management of osteoarthritis

■ ROY D. ALTMAN ■ MARC C. HOCHBERG

- Osteoarthritis (OA) is the most common form of arthritis, and pain is its most common symptom.
- Currently, the aims of treatment are to reduce pain and improve function and health-related quality of life.
- Management of OA should be individualized and requires a combination of nonpharmacologic and pharmacologic modalities.
- Patient education, weight control, and exercise are the cornerstones of successful nonpharmacologic management of OA.
- Oral and topical pharmacologic therapies, including acetaminophen, nonsteroidal antiinflammatory drugs, and nonopioid analgesics, are often effective in relieving pain.
- Intraarticular agents, including corticosteroids and hyaluronate products, may be useful in the symptomatic treatment of hip and knee OA.
- The adverse event profile of the therapeutic plan should be minimized whenever possible and be consistent with the values and preferences of the patient.
- Pharmacologic structure-modifying interventions are currently under active investigation.
- Surgical interventions are available for patients whose disease fails to respond to nonpharmacologic interventions.

INTRODUCTION

Osteoarthritis (OA) comprises a heterogeneous group of conditions with a variety of patterns of expression.^{1,2} OA can be conceptualized as an illness with a constellation of symptoms, including pain, aching, discomfort, stiffness, fatigue, and sleep disturbance; the symptoms of OA are reviewed in Chapter 173. OA can also be described as a disease characterized by pathologic changes in articular cartilage and subchondral bone with variable degrees of local synovitis; the pathology of OA is reviewed in Chapter 175. Before initiating therapy the diagnosis of OA should be confirmed by history and physical examination, plus conventional radiographic imaging if necessary. Presently, management of patients with OA is focused on the following goals:

- Relieving symptoms, including pain
- Limiting physical dysfunction by maintaining or improving joint mobility
- Improving health-related quality of life

Management of OA comprises two aspects:

- The first is assessment of OA patients: What data should be collected to help in the therapeutic decision? How should such data be collected?
- The second is treatment of OA: What therapeutic modalities are available? What are their optimal indications? What are their potential benefits and risks?

Assessment of patients with OA in both clinical practice and clinical research is reviewed in Chapter 178. The remainder of this chapter focuses on the nonpharmacologic and pharmacologic modalities available for use in patients with symptomatic OA, with comments on surgical alternatives. The treatment modalities are presented in the context of recommendations for management published by the American College of Rheumatology

(ACR) in 2012³ and the Osteoarthritis Research Society International (OARSI) in 2008 (Fig. 181.1 and Box 181.1).⁴⁻⁶ Readers should be aware of other recommendations reviewed by the ACR in 2012, including but not limited to those published by the European League Against Rheumatism (EULAR),⁷⁻⁹ the National Institute for Clinical Excellence (NICE) in the United Kingdom, and the American Academy of Orthopaedic Surgeons (AAOS).^{10,11}

TREATMENT MODALITIES

Objectives

Treatment aims for patients with OA include (1) education about OA, (2) reduction of pain, (3) optimization and maintenance of physical function, and (4) attempts to prevent or slow the progression of structural damage (e.g., cartilage, bone, ligament, muscle). Currently available treatments include a wide range of nonpharmacologic, pharmacologic, and surgical modalities. The OARSI recommendations for the management of hip and knee OA used an evidence-based and experts' consensus opinion approach (Box 181.2).⁵ The ACR guidelines were developed by using the Grading of Recommendations Assessment, Development and Evaluation method, a process that rates existing scientific evidence with an expert panel to develop evidence-based recommendations. The ACR recommendations emphasize different nonpharmacologic and pharmacologic treatment modalities that are joint-specific and extend previously published EULAR recommendations for hand, hip, and knee OA,⁷⁻⁹ including both nonpharmacologic and pharmacologic therapies. Treatment of OA at other sites is not discussed.

Optimal management of patients involves a combination of both nonpharmacologic and pharmacologic modalities individualized to the patient's values and preferences. We first review the nonpharmacologic modalities, which serve as the basis for the patient's treatment, and then the pharmacologic modalities, which can be added as necessary for additional control of symptoms. It should be pointed out that in most patients a single therapeutic modality may not provide an adequate clinical response. Despite the lack of adequate clinical trials, multimodal therapy—a combination of at least one nonpharmacologic modality in addition to at least one pharmacologic modality—is commonly employed for treatment of individual patients. A pyramid approach to the management of patients with lower limb OA based on the ACR recommendations is shown in Figure 181.1.

Nonpharmacologic modalities

Patient education

Despite the widespread recommendation that patient education be part of the basic program for the management of patients with symptomatic OA, the supporting evidence suggests only a weak effect of patient education, including cognitive-behavioral therapy, on pain and functional limitation.^{12,13}

Exercise

A physical exercise program should have the following objectives: reduce pain, increase or maintain range of articular motion, increase or maintain muscular strength, improve mobility and physical activity, and reduce activity and functional limitations. There have been numerous systematic reviews of randomized, controlled trials of different exercise programs in patients suffering from hip or (more frequently) knee OA.¹⁴⁻¹⁹ These reviews concluded that there is high-quality evidence that programs of exercise therapy, be they aquatic (water based), aerobic (land-based), or resistance in nature, are able to decrease pain and improve functional capacity in patients with OA. The

Fig. 181.1 Management of symptomatic lower limb osteoarthritis (OA) based on the 2012 American College of Rheumatology recommendations. COX-2 SI, cyclooxygenase-2-selective inhibitor; NSAIDs, nonsteroidal antiinflammatory drugs; OTC, over the counter; TCA, tricyclic antidepressant; TENS, transcutaneous electrical nerve stimulation.

BOX 181.1 OARSİ RECOMMENDATIONS FOR THE MANAGEMENT OF PATIENTS WITH HIP OR KNEE OSTEOARTHRITIS

Nonpharmacologic therapies

- Patient education
- Self-management
- Aerobic exercise
- Strengthening exercise
- Water-based exercise
- Weight loss
- Insoles
- Braces
- Patellar taping
- Cane/stick
- Telephone contact
- Massage
- Local heat/ice
- Acupuncture
- Transcutaneous electrical nerve stimulation
- Yoga
- Low-energy lasers
- Ultrasound

Pharmacologic therapies

- Acetaminophen (paracetamol)
- Nonsteroidal antiinflammatory drugs
- Cyclooxygenase-2-selective inhibitors
- Topical nonsteroidal antiinflammatory drugs
- Topical capsaicin
- Opioid analgesics
- Diacerein
- Glucosamine sulfate
- Chondroitin sulfate
- Avocado/soybean unsaponifiables
- Intraarticular corticosteroids
- Intraarticular hyaluronic acid preparations
- Herbal compounds
- Oral corticosteroids

Surgical interventions

- Joint lavage
- Arthroscopic débridement
- Osteotomy
- Total articular replacement
- Knee fusion

OARSİ, Osteoarthritis Research Society International.

treatment effects observed (i.e., improvement over the control group) are usually moderate (effect sizes ranging from 0.4 to 0.6) and typically occur after 3 to 6 months of therapy. Numbers needed to treat are in single digits. The evidence is generally stronger for knee OA than for hip OA.

Exercise programs should include manual therapy such as stretching exercises and soft tissue mobilization aimed at maintaining or improving range of motion, along with exercises aimed at improving muscle

performance in terms of dimension and strength.²⁰ Such exercises should be adapted according to the presence or absence of a painful episode of OA. During painful episodes, isometric exercises such as quadriceps contraction or exercises in a nonloading position (cycling, rowing with adapted tools) or in a partial nonloading position (aquatic exercises) should be proposed. During painless (or at least less painful) periods, the exercise program could include stretching and muscle performance exercises.

Whatever the type of exercise prescribed, they should be performed at least three to five times per week. Efficacy is better in compliant patients. Therefore, it seems that regular interventions, such as telephone calls and visits to physiotherapists, are important to ensure long-term adherence to the exercise program.

Weight loss

Weight loss is recommended for all patients with symptomatic lower limb OA who are overweight.^{21,22} Overall, evidence is strong that weight loss of at least 5% of body weight is associated with a small but significant improvement in both pain and physical function. Obviously, because of the common occurrence of comorbid cardiovascular and metabolic conditions such as hypertension, diabetes mellitus, and coronary artery disease, weight reduction is important not only for the patient's OA but also for general health and well-being.

Orthotics

Orthotics are used mainly to improve symptoms but might also help correct abnormal biomechanical forces operating across the joint. The type of orthotic used is obviously joint specific. The use of foot orthoses in patients with knee OA is controversial.²³⁻²⁶ There is no compelling evidence at this time that the use of orthotics reduces progression of structural damage in patients with knee OA.

Braces and patellar taping

As with orthotics, braces are used mainly to improve symptoms but might also help correct abnormal biomechanical forces operating across the joint. The efficacy of bracing remains controversial because few published randomized controlled trials have provided convincing evidence for the use of bracing in patients with knee OA.^{23,27} Neither the ACR nor the AAOS was able to make recommendations for or against the use of braces for symptomatic treatment of knee OA.^{3,11} Medial patellar taping, however, is efficacious in relieving pain, although it is frequently accompanied by minor skin irritation from the tape itself.²⁷ The patient should be instructed in taping by a physical therapist.

Use of assistive devices

In patients with weight-bearing joint pain, appropriate use of a cane, crutch, or walker could be a useful adjuvant therapy. A cane or single crutch should be held on the side contralateral to the affected hip or knee and be advanced with the affected limb when walking to effectively reduce load on the affected joint—the tip should be changed regularly. A useful length of cane is the distance from the floor to the patient's greater trochanter; this brings the elbow into 15 to 20 degrees of flexion. Ideally, the patient should be fitted for a cane and instructed in its use by a physical therapist. The same principles apply to a walker.

Other nonpharmacologic interventions

A number of other nonpharmacologic interventions have been conditionally recommended by the ACR for patients with knee OA, including tai chi, transcutaneous electrical nerve stimulation (TENS), and traditional Chinese acupuncture.²⁸⁻³²

The ACR suggests that both TENS and traditional Chinese acupuncture be reserved for patients who are candidates for total joint arthroplasty (see later) but are either unwilling to undergo or have medical contraindications to these procedures.³

Pharmacologic treatment modalities

Topical agents

The most widely used topical agents are preparations containing capsaicin, lidocaine, and nonsteroidal antiinflammatory drugs (NSAIDs). Capsaicin preparations have been shown to be efficacious in controlled double-blind studies of OA of the hand and knee. Some of the topical NSAIDs have demonstrated benefit in double-blind placebo-controlled trials of knee and hand OA.³³⁻³⁵ Furthermore, topical NSAIDs have been shown to be efficacious as orally administered NSAIDs and to have a lower incidence of upper gastrointestinal side effects.^{34,35} It is clear that topical agents should be considered a useful, if not first-line option in patients with symptomatic knee

BOX 181.2 OARS RECOMMENDATIONS FOR THE MANAGEMENT OF PATIENTS WITH HIP OR KNEE OSTEOARTHRITIS

- Optimal management of osteoarthritis (OA) requires a combination of nonpharmacologic and pharmacologic modalities.
- All patients with hip and knee OA should be provided access to information and education about the objectives of treatment and the importance of changes in lifestyle, exercise, pacing of activities, weight reduction, and other measures to unload the damaged joint or joints. The initial focus should be on self-help and patient-driven treatments rather than on passive therapies delivered by health care professionals. Subsequently, emphasis should be placed on encouraging adherence to the regimen of nonpharmacologic therapy.
- The clinical status of patients with hip or knee OA can be improved if they are contacted regularly by telephone.
- Patients with symptomatic hip and knee OA may benefit from referral to a physical therapist for evaluation and instruction in appropriate exercises to reduce pain and improve functional capacity. This evaluation may result in the provision of assistive devices such as canes and walkers, as appropriate.
- Patients with hip and knee OA should be encouraged to undertake—and continue to undertake—regular aerobic, muscle-strengthening, and range-of-motion exercises. For patients with symptomatic hip OA, exercises in water can be effective.
- Patients with hip and knee OA who are overweight should be encouraged to lose weight and maintain their weight at a lower level.
- Walking aids can reduce pain in patients with hip and knee OA. Patients should be given instruction in the optimal use of a cane or crutch with the contralateral hand. Frames or wheeled walkers are often preferable for those with bilateral disease.
- In patients with knee OA and mild to moderate varus or valgus instability, a knee brace can reduce pain, improve stability, and diminish the risk of falling.
- Every patient with hip or knee OA should receive advice concerning appropriate footwear. In patients with knee OA, insoles can reduce pain and improve ambulation. Lateral-wedged insoles can be of symptomatic benefit for some patients with OA in the medial tibiofemoral compartment.
- Some thermal modalities may be effective in relieving symptoms in patients with hip and knee OA.
- Transcutaneous electrical nerve stimulation can help in short-term pain control in some patients with hip or knee OA.
- Acupuncture may be of symptomatic benefit in patients with knee OA.
- Acetaminophen (up to 4 g/day) can be an effective initial oral analgesic for the treatment of mild to moderate pain in patients with knee or hip OA. In the absence of an adequate response or in those with severe pain or inflammation, alternative pharmacologic therapy should be considered on the basis of relative efficacy and safety, as well as concomitant medications and comorbid conditions.
- In patients with symptomatic hip or knee OA, nonsteroidal antiinflammatory drugs (NSAIDs) should be used at the lowest effective dose, but long-term use of such drugs should be avoided if possible. In patients with increased gastrointestinal risk, either a cyclooxygenase-2 (COX-2)-selective agent or a nonselective NSAID with coprescription of a proton pump inhibitor or misoprostol for gastroprotection should be considered, but NSAIDs, including both nonselective and COX-2-selective agents, should be used with caution in patients with cardiovascular risk factors.
- Topical NSAIDs and capsaicin can be effective as adjunctive agents and alternatives to oral analgesic/antiinflammatory drugs for knee OA.
- Intraarticular injections of corticosteroids can be used for the treatment of hip or knee OA and should be considered particularly when patients have moderate to severe pain not responding satisfactorily to oral analgesic/antiinflammatory agents and in those with symptomatic knee OA with effusions or other physical signs of local inflammation.
- Intraarticular injection of hyaluronate may be useful in patients with knee or hip OA. They are characterized by delayed onset, but prolonged duration of symptomatic benefit when compared with intraarticular injection of corticosteroids.
- Treatment with glucosamine or chondroitin sulfate (or with both) may provide symptomatic benefit in patients with knee OA. If no response is apparent within 6 months, treatment should be discontinued.
- In patients with symptomatic knee OA, glucosamine sulfate and chondroitin sulfate may have structure-modifying effects, whereas in those with symptomatic OA of the hip, diacerein may have structure-modifying effects.
- The use of weak opioids and narcotic analgesics can be considered for the treatment of refractory pain in patients with hip or knee OA when other pharmacologic agents have been ineffective or are contraindicated. Stronger opioids should be used only for the management of severe pain in exceptional circumstances. Nonpharmacologic therapies should be continued in such patients and surgical treatments considered.
- Patients with hip or knee OA who are not obtaining adequate pain relief and functional improvement from a combination of nonpharmacologic and pharmacologic treatment should be considered for joint replacement surgery. Replacement arthroplasty is an effective and cost-effective intervention for patients with significant symptoms or functional limitations associated with a reduced health-related quality of life despite conservative therapy.
- Unicompartmental knee replacement is effective in patients with knee OA restricted to a single compartment.
- Osteotomy and joint-preserving surgical procedures should be considered in young adults with symptomatic hip OA, especially in those with dysplasia. For young and physically active patients with significant symptoms from unicompartmental knee OA, high tibial osteotomy may offer an alternative intervention that delays the need for joint replacement for possibly 10 years.
- The role of joint lavage and arthroscopic débridement in knee OA is controversial. Although some studies have demonstrated short-term relief of symptoms, others suggest that improvement in symptoms could be attributable to a placebo effect.
- In patients with OA of the knee, joint fusion can be considered as a salvage procedure when joint replacement has failed.

OARS, Osteoarthritis Research Society International.

OA, particularly in the elderly.³⁶ Short-term trials have suggested benefit from topical lidocaine patches. There are no published clinical trials of the many nonprescription topical agents or topical corticosteroids.

Oral analgesics

Acetaminophen (paracetamol)

Acetaminophen (paracetamol) is recommended for symptomatic treatment of patients with OA and mild to moderate pain by several societies because of its efficacy, safety, and cost. Several systematic reviews and meta-analyses of randomized placebo-controlled trials of acetaminophen for knee OA showed a small, but significant effect in relieving pain without an accompanying effect on either functional improvement or stiffness.^{6,33,34,37}

The safety profile of acetaminophen has been revisited, in particular when considering a 4000-mg daily dose. The results of a pharmacoepidemiologic study suggest that high (≥ 3000 mg) doses of acetaminophen may convey the same risk for upper gastrointestinal complications as traditional nonselective NSAIDs.³⁸ Similarly, the results of observational studies suggest that chronic use of acetaminophen may convey the same risk for hypertension as traditional NSAIDs.³⁹ Acetaminophen is a weak inhibitor of both cyclooxygenase-1 (COX-1) and COX-2, which is the reason for its apparent upper gastrointestinal and renovascular toxicity, although selection bias in study design cannot be excluded.⁴⁰ In addition, one should be cautious

when combining acetaminophen with oral NSAIDs; however, the combination of acetaminophen and topical NSAIDs can be used.

Another particular concern is the concomitant use of acetaminophen with over-the-counter combination products that also contain acetaminophen. Indeed, acetaminophen is the most common cause of drug-induced liver failure, as well as the need for hepatic transplantation, in the United States. Hence, an Advisory Committee of the U.S. Food and Drug Administration recommended that the maximal single daily dose of acetaminophen be lowered to 3000 mg and that combination products containing acetaminophen, including acetaminophen-opioid analgesics, be removed from the market. High-dose acetaminophen has also been associated with a prolonged prothrombin time in patients undergoing coumarin anticoagulation.

Nonsteroidal antiinflammatory agents

NSAIDs are used widely for the management of OA. A detailed description of their mechanism of action and the potential gastrointestinal, renal, and cardiovascular toxicity observed in clinical trials and observational studies can be found in Chapter 53. In addition, readers are referred to a “white paper” published by the ACR on the use of NSAIDs⁴¹ and the Safety of Nonsteroidal Anti-inflammatory Drugs website (www.sos-nsaids-project.org) for results from the European Union-funded pharmacoepidemiology project.

Systematic reviews of randomized placebo-controlled clinical trials that evaluated the use of NSAIDs for OA clearly demonstrate moderate short-term efficacy in comparison to placebo, although this appears to be magnified with use of the “flare” study design.^{6,33,34}

Nonsteroidal antiinflammatory drugs versus acetaminophen. A systematic review and meta-analysis found NSAIDs to be more efficacious than acetaminophen for OA-related pain, yet the risk associated with discontinuing therapy because of gastrointestinal adverse events was approximately 50% higher with traditional NSAIDs than with acetaminophen.³⁷ Furthermore, the majority of patients with OA expressed a preference for NSAIDs over acetaminophen. Hence, NSAIDs are a reasonable alternative to acetaminophen, especially in patients with OA and moderate to severe pain.

Cyclooxygenase-2-selective inhibitors versus traditional nonselective nonsteroidal antiinflammatory drugs. A systematic review of randomized trials of OA to evaluate the COX-2-selective inhibitors celecoxib, rofecoxib, valdecoxib, etoricoxib, and lumiracoxib concluded that efficacy was comparable between these agents, as well as equivalent doses of traditional nonselective NSAIDs.⁴² Only two COX-2-selective inhibitors are presently available, celecoxib and etoricoxib. They are indicated primarily in patients at increased risk for symptomatic gastrointestinal ulcers and complicated upper gastrointestinal events, including perforation and bleeding.⁴³ Their use in patients either receiving concomitant antiplatelet therapy or with cardiovascular risk factors has been the subject of several published recommendations by specialty societies.⁴⁴⁻⁴⁶ Perhaps the safest and most cost-effective approach for OA patients at risk for complicated upper gastrointestinal events is to use a COX-2-selective inhibitor in combination with a proton pump inhibitor. The same gastrointestinal ulcer protection has not been demonstrated with other antiulcer regimens.^{47,48} A comprehensive individual patient data meta-analysis of the cardiovascular and gastrointestinal safety of COX-2-selective inhibitors was published in August 2013 and demonstrated a modest increased risk for cardiovascular thrombotic events other than stroke, congestive heart failure, all-cause and cardiovascular-specific mortality and upper gastrointestinal bleeding compared to placebo.⁴⁹

Centrally acting analgesics

Duloxetine, a dual serotonin and norepinephrine reuptake inhibitor, was shown to be efficacious in relieving chronic knee pain in patients with OA.⁵⁰ It can be used either alone or in combination with NSAIDs in patients with persistent pain.⁵¹ Tramadol (a weak μ -opioid antagonist and serotonin reuptake inhibitor) is also efficacious in patients with OA either alone or in combination with acetaminophen or NSAIDs.⁵² The drug should be started at a low dose (50 mg once daily) and titrated upward slowly to minimize potential adverse events, especially in the elderly.⁵³

Opioid analgesics have been shown to be efficacious for short-term pain relief in patients with OA; however, they are rarely indicated for long-term therapy.^{54,55} Indeed, long-term use should be restricted to patients who continue to have severe pain and are either not candidates for or are unwilling to undergo total joint arthroplasty.⁴ Opioid analgesics have severe potential side effects, including falls and fractures, which is particularly of special clinical relevance in elderly patients.^{56,57} Principles underlying the use of opioid analgesics for chronic musculoskeletal pain are reviewed in Chapter 52. The American Academy of Pain Management and the American Pain Society have published recommendations for the use of opioid analgesics for chronic noncancer pain; these recommendations should be followed by all practitioners who are considering the use of opioid analgesics in their patients with OA.⁵⁸

Intraarticular therapy

Corticosteroids

Intraarticular depot corticosteroids are recommended in several guidelines for the management of patients with OA. Several systematic reviews and meta-analyses support the efficacy and safety of intraarticular steroids for hip and knee OA.⁵⁹⁻⁶¹ Onset of efficacy is rapid, with maximal efficacy reached in less than 1 week; the response lasts only 4 weeks in randomized controlled trials but often 3 months or longer in clinical practice. There is limited evidence that the presence of an effusion leads to a better response to intraarticular depot corticosteroids. However, in our opinion the presence of a knee effusion reflects an inflammatory synovitis, thus justifying the use of intraarticular depot corticosteroids.

Adverse events following intraarticular injection are uncommon.⁶² A placebo-controlled trial of repeated intraarticular steroid injections given every 3 months for 2 years demonstrated no particular detectable side effect or change in joint space width when compared with intraarticular saline.⁶³

Hyaluronate preparations

Viscosupplementation refers to the intraarticular injection of preparations of hyaluronic acid, a high-molecular-weight polysaccharide that is a major component of normal synovial fluid and cartilage, to relieve pain and improve function. Many hyaluronate preparations are currently available; there are differences in molecular weight, viscosity, origin (avian or bacterial), presence or absence of cross-linkage, and number of injections in each series. Several systematic reviews have evaluated the randomized controlled trials of intraarticular hyaluronan preparations, often with differing results.^{6,64-70} The main conclusions are that a course of intraarticular hyaluronic acid injections is associated with a small, but significant symptomatic effect lasting up to 26 weeks in comparison to intraarticular saline injections. Adverse events include the occasional injection site reaction and rare flare of pseudogout. Pseudoseptic reactions and granuloma formation have been reported mostly with cross-linked products.

Slow-acting symptomatic osteoarthritic drugs

Pharmaceutical compounds other than analgesics and NSAIDs have been licensed for the management of OA in Europe but not in the United States. The main differences between these compounds and NSAIDs follow:

- Delayed onset of action
- Carryover effect after use of the compound is discontinued
- Potential beneficial structural (disease-modifying) effect

Diaceirin

Diaceirin is an anthraquinone derivative that has been shown to inhibit the production of interleukin-1 (IL-1) and reduce cartilage breakdown and the development of cartilage lesions in preclinical models of OA. Two systematic reviews of randomized placebo-controlled trials demonstrated efficacy in comparison to placebo, with a small but significant effect size; the major adverse event was diarrhea, which was dose dependent.^{71,72}

The potential structural effect of diaceirin was investigated in a 3-year placebo-controlled trial involving 507 patients suffering from painful hip OA.⁷³ Radiographic progression (i.e., a decline in joint space width of at least 0.5 mm during the study) was significantly reduced in the diaceirin-treated group when compared with the placebo group. This reduction in radiographic progression was accompanied by a 25% reduction in the occurrence of total hip replacement; this reduction did not reach statistical significance, though, perhaps because of small numbers of events.

Glucosamine sulfate

Glucosamine is commercially derived from chitin, the specially processed exoskeleton of shrimp, lobster, and crab. Crystalline glucosamine sulfate is available commercially as a pharmaceutical drug in Europe; however, it is not registered in the United Kingdom or the United States. Evidence from systematic reviews of randomized placebo-controlled trials suggests that crystalline glucosamine sulfate, marketed as a pharmacologic agent in Europe (see earlier), is efficacious in the treatment of knee OA, whereas glucosamine preparations, including glucosamine hydrochloride, available as nutritional supplements in the United Kingdom and North America, are not.^{6,68,74-76} Reasons for this difference are unclear.

Two placebo-controlled randomized trials were conducted to assess the structure-modifying effect of crystalline glucosamine sulfate in patients with knee OA.^{77,78} Both showed a statistically significant reduction in the decline in joint space narrowing with glucosamine sulfate in comparison to placebo. A follow-up of patients who participated in these trials suggested that 3 years of glucosamine therapy might result in a reduced requirement for knee surgery.⁷⁹

Because of these findings (on one hand, positive symptomatic effect, positive structural effect, and long-term clinically relevant effect such as a reduction in the requirement for surgery and, on the other hand, potential biases of the reported studies⁷⁴⁻⁷⁶) and also because of the importance of the consequences for management of patients in daily practice, the National Institutes of Health (NIH) sponsored a large (3238 patients) multicenter U.S. study on painful knee OA (the GAIT trial).⁸⁰ This study was designed *a priori* to be split into two parts: the first 6 months for evaluation of their effect on symptoms and the following 24 months for evaluation of their effect on both symptoms and structure. The study design included five arms: placebo, celecoxib 200 mg daily (active control), glucosamine hydrochloride 500 mg three times per day, chondroitin sulfate 400 mg three times per day, and the combination of glucosamine plus chondroitin sulfate. When compared with placebo, there was a statistically significant difference in the primary outcome variable (i.e., response defined by at least 20% improvement in pain) in favor of celecoxib (70.4% vs. 60.1% responder rate), but no statistically significant difference in favor of glucosamine, chondroitin

sulfate, or the combination (percentage of responders: 64.0%, 65.4%, 66.6%, respectively). However, a predefined subgroup analysis performed in patients with severe pain at entry did demonstrate a statistically significant difference for the combination (glucosamine plus chondroitin sulfate) versus placebo (percentage of responders: 79.2% vs. 54.3%, respectively), but not for celecoxib versus placebo. Regarding long-term structural effects, no significant differences were found between groups in the rate of decline in joint space width over a period of 2 years.⁸¹ Hence, if a practitioner decides to use glucosamine for the treatment of symptoms and structure modification in patients with knee OA, the glucosamine sulfate preparation approved as a pharmaceutical agent in Europe should be used. A noninferiority trial of a fixed-dose combination of glucosamine hydrochloride and chondroitin sulfate (Droglican, Bioiberica S.A., Barcelona) versus celecoxib is in progress in several European countries; results are expected in 2014.

Chondroitin sulfate

Chondroitin sulfate is a macromolecule that provides (like hyaluronic acid) the framework for collagen formation. The rationale for use and information on the data available for symptomatic efficacy are similar to that discussed for glucosamine sulfate for relief of symptoms in patients with knee OA.^{6,68,76,82} A systematic review of randomized double-blind placebo-controlled trials did demonstrate a significant but small effect on slowing the rate of decline in joint space width in patients with knee OA.^{83,84} This result was robust to the inclusion of data from GAIT, even though the latter study did not demonstrate significance by itself.⁸¹ As with glucosamine sulfate, chondroitin sulfate seems to be very safe. The recommended dose is 800 mg once daily.

Avocado/soybean unsaponifiables

Avocado/soybean unsaponifiables (ASUs) can be considered either as a supplement or as a drug. Despite the fact that ASUs are commonly used for both hip and knee OA in France, evidence of its efficacy is only fair and the effect size is small.⁸⁵

Surgical interventions

Surgical interventions for OA can be categorized into three groups based on the rationale or the main objective of the treatment: (1) improving current symptoms (e.g., lavage and joint débridement); (2) preventing the risk for structural progression (e.g., osteotomy); and (3) improving the symptoms related to advanced disease (e.g., joint arthroplasty or replacement).

Arthroscopic or tidal lavage and joint débridement

In theory, lavage of the joint (through a large needle or by arthroscopy) removes debris, including microscopic or macroscopic fragments of cartilage or calcium pyrophosphate crystals, that may induce synovitis, a probable source of pain. Tidal irrigation is a similar procedure but uses only one entry site. Arthroscopic débridement consists of smoothing rough, fibrillated articular and meniscal surfaces, shaving tibial spine osteophytes that interfere with motion of the joint, and removing inflamed synovium. Several randomized controlled trials of arthroscopic débridement with lavage have not demonstrated efficacy in comparison to either sham surgery or usual

care in unselected patients with knee OA.^{61,86-88} The exact place of arthroscopic débridement and lavage in treating knee OA, if any, remains to be established; it may be indicated only in patients with symptoms and signs of internal derangement, including meniscal tears.

Osteotomy

Malalignment has been recognized as the most important predisposing factor to further structural progression in knee OA. Therefore, correction of this abnormality through either bracing or surgery has potential for structure modification. Observational studies suggest that osteotomy could be considered in patients with either mild to moderate medial tibiofemoral OA with varus malalignment or moderate superolateral hip OA with evident hip dysplasia.⁸⁹ However, lack of evaluation of the safety and long-term efficacy of this treatment modality precludes any formal recommendation, which explains the huge intercountry variability in use of this treatment. A randomized trial comparing high tibial osteotomy and unicompartmental knee replacement in patients with medial compartment knee OA and varus malalignment is in progress in Europe.

Total joint arthroplasty

Articular replacement is considered the “gold standard” because it is very effective in providing pain relief and restoring function in many patients with hip and knee OA. Consensus conferences sponsored by the NIH have proposed consensus criteria for total articular replacement in patients with hip and knee OA; in general, the indication for surgery is based on the severity of the patient's pain and functional limitation, the impact of OA on health-related quality of life, and the presence of moderate to severe radiographic features of OA.^{90,91} In daily practice, the decision should include consideration of the patient's comorbid medical conditions and willingness to undergo the procedure.

Recommendations for the management of hand osteoarthritis

Recommendations for the management of hand OA were published by the ACR in 2012³ and by the EULAR in 2007.⁹ Several systematic reviews of nonsurgical therapies for hand OA were used as the basis for the ACR recommendations.⁹²⁻⁹⁵ The data suggest that there is some evidence to support the efficacy of occupational therapy, including instruction in joint protection techniques and the use of assistive devices and thermal modalities; splinting of the first carpometacarpal (CMC) joint and topical therapies, including capsaicin and NSAIDs; oral NSAIDs, including COX-2-selective inhibitors; and tramadol. Hydroxychloroquine may be efficacious in patients with inflammatory interphalangeal joint OA who have not responded adequately to topical or oral NSAIDs; neither sulfasalazine nor methotrexate are recommended in this situation. Intraarticular injections of corticosteroid and hyaluronate preparations are not more efficacious than saline injections for OA of the first CMC joint. Trials of tumor necrosis factor inhibitors failed to demonstrate efficacy in patients with erosive hand OA either for symptomatic or for structural outcomes.⁹⁶ Trials of monoclonal antibodies to IL-1 for hand OA are in progress.

Diffuse idiopathic skeletal hyperostosis

■ GEOFFREY LITTLEJOHN

- Diffuse idiopathic skeletal hyperostosis is a chronic, age-related condition characterized by new bone growth, especially at entheses.
- Radiologic findings are characteristic.
- Hyperostosis results in an increase in bone mass.
- Few symptoms are related to diagnostic changes in the thoracic spine.
- Hyperostosis carries the risk of important cervical and lumbar arthropathy, enthesopathy, and neural impingement.
- An association exists with obesity, type 2 diabetes, gout, dyslipidemia, hypertension, hyperinsulinemia, and other features of metabolic syndrome.
- Growth factors, particularly insulin, are implicated in the disorder.

HISTORY

Diffuse idiopathic skeletal hyperostosis (DISH), also known as *ankylosing hyperostosis* or *Forestier disease*, is a ubiquitous skeletal condition affecting many species and most human populations studied. Forestier and Rotes-Querol¹ first presented comprehensive anatomic, radiologic, and clinical data on the disorder, which was then termed *ankylosing hyperostosis*. The condition is seen as a well-defined syndrome with both axial and peripheral manifestations. The diffuse nature of the condition later led to use of the term *diffuse idiopathic skeletal hyperostosis*.²

EPIDEMIOLOGY

There is a 2:1 reported male predominance in DISH, with the prevalence in both sexes rising with age and weight (Fig. 182.1)^{3,4}; the condition is uncommon before the age of 45 years.⁵

Although diagnostic criteria vary, population surveys indicate that DISH is a common condition. In Scandinavia the annual cumulative incidence is estimated to be 7 per 1000 in men and 4 per 1000 in women beyond the age of 30.⁶ Prevalence rates vary in different populations but are consistent with these findings.⁷ Approximately 10% to 15% of men and 5% to 10% of women older than age 65 have DISH, although some populations have an increased predisposition for the disorder (Table 182.1).^{8,9} It is possible that the prevalence is increasing in some of these populations.¹⁰

CRITERIA AND CHARACTERISTIC DESCRIPTION

Criteria for the diagnosis of DISH rely principally on radiologic findings in the thoracic spine. These criteria typically require new bone formation to bridge four contiguous vertebral bodies in the absence of both degenerative disk disease and inflammatory sacroiliac or facet joint changes.¹¹ In routine clinical practice, however, it is more common to see significant age-related disk or facet joint degenerative changes occurring in conjunction with changes of DISH. Thus study populations of “pure” DISH may differ in clinical characteristics from those with DISH occurring in conjunction with other common degenerative spinal conditions.

The condition is characterized by widespread new bone formation, with an increase in the amount of normal new bone, heterotopic bone formation,

and specifically the presence of new bone growth into the enthesal regions (Fig. 182.2). The enthesis is that region where the tendon, ligament, joint capsule, or annulus fibrosus fibers insert into bone.¹² Although it was the prominent new bone growth in the anterolateral enthesal regions along the thoracic spine that first brought attention to this condition, it may affect any skeletal structure to differing degrees.

DISH changes are most characteristic in the thoracic spine, where uninterrupted new bone may “flow” from one vertebra to another. It is more prominent on the right side of the thoracic vertebra, which is thought to be a consequence of the pressure effect of the left-sided aorta. The presence of the anterior longitudinal ligament over the anterior two thirds of the vertebral bodies dictates the distribution of the new bone formation. There is often a gap in the new bone adjacent to the intervertebral disk or between the new bone and the intact original cortex. When disk changes are absent, the newly formed bone may be applied close to the vertebral bodies and can, at times, mimic an inflammatory spondylitis. In DISH the original cortex remains under the ossified ligament, whereas in spondylitis erosion of the cortex is characteristic, particularly at the vertebral corners, and underlying sclerosis is present when the inflammation is active. DISH may coexist with spondylitis or any other condition. In particular, because the condition is more prominent with increased age, it commonly coexists with intervertebral disk disease, and in such situations the bulging of the disk material anteriorly may give rise to dramatic anterior spinal hyperostotic change. In the more mobile cervical and lumbar spine regions, hyperostotic changes are more characteristic than simple bridging, and spinal stenosis may result.

There is a spectrum of spinal new bone formation, with increasing amounts laid down with increasing duration.⁴ The well-defined condition occurs over several years, but regression of new bone growth over a short period has been noted in the context of a pressure effect from an enlarging aortic aneurysm.¹³ The spinal new bone formation appears to be a dynamic process, with deposition and remodeling likely similar to that which occurs in other skeletal areas. Peripheral new bone formation is also more prominent in the enthesal areas, particularly around heels, knees, and elbows, among other regions. Such changes also occur on a spectrum ranging from minor to quite marked hyperostosis.¹⁴ Pronounced peripheral hyperostosis may precede spinal changes diagnostic of DISH. All of these changes appear to be part of the one condition; however, the diagnosis of DISH currently rests on characteristic findings in the spine and not in the periphery.

The “diffuse hyperostosis” of DISH includes increased bone formation as demonstrated by phalangeal tufting, increased cortical thickness of tubular bones of the hand, and an increase in the size of the sesamoid bones.¹⁵ Increased bone mineral density has been noted in the spine when dual energy x-ray absorptiometry is used, possibly due to the effects of increased enthesal ossification,¹⁶ but quantitative computerized tomographic techniques have shown no differences in peripheral bone density or geometry.¹⁷

Heterotopic new bone formation after surgical procedures, such as total hip replacement, may occur in DISH.¹⁸

DISH may coexist with inflammatory joint diseases such as rheumatoid arthritis, psoriatic arthritis, spondyloarthritis, or gout. It has been shown to modify the radiologic reaction to rheumatoid arthritis, with less destructive bone disease and a tendency for erosions to heal more quickly.¹⁹ There is an increased prevalence of DISH in patients with gout and Paget disease.^{9,20}

CLINICAL FEATURES

The process of new bone deposition in DISH is asymptomatic.²¹ However, the consequences of new bone growth in areas described earlier may cause

Fig. 182.1 Occurrence of diffuse idiopathic skeletal hyperostosis (DISH) in the thoracic spine in different age groups. Data are from 296 individuals at autopsy.¹³ Mild, enthesal new bone present at two or more levels; moderate, continuous new bone spanning fewer than four levels; severe, continuous new bone spanning four or more levels (typical DISH). See also Fig. 182.6.

TABLE 182.1

Prevalence of diffuse idiopathic skeletal hyperostosis

Population	Prevalence
White populations (various studies) ¹⁴⁻¹⁶	Men 10% Women 8%
Pima Indians ¹⁷	Men 54% Women 14%
Men with gout ¹⁸	58%

*Table gives the prevalence of diffuse idiopathic skeletal hyperostosis at age 65 years or older (selected studies¹⁴⁻¹⁸).
Diagnostic criteria vary slightly.*

increased stiffness in neck, back, or peripheral joints.^{22,23} Tight spinal structures may also increase regional symptoms, including tenderness.²⁴

In peripheral joints, a stiffening arthropathy due to thickening and shortening of ligaments has been described long before the characteristic spinal changes appear.²² Clinically, there may be painless reduction of internal rotation of shoulders and hips and reduced flexion of fingers and knees.

Pain may be present in some patients who have peripheral enthesopathy (e.g., from a calcaneal spur), most likely because abnormal biomechanical stress causes injury to the enthesis. However, although the majority of such extraspinal enthesal changes are asymptomatic, adequate controlled studies are lacking.

Important clinical features arise when new bone growth obstructs or impinges on other tissues. In the cervical spine DISH may give rise to dysphagia²⁵ or cervical myelopathy.²⁶ Association with ossification of the posterior longitudinal ligament²⁷ can result in myelopathy and even quadriplegia. In the lumbar spine, spinal stenosis may occur secondary to posterior osteophytic ridges and facet arthropathy with marked hyperostosis.

Uncommonly, fractures through bony bridges may occur; if so, they may be difficult to diagnose and treat.²⁸

DISH is associated with a particular type of hip disease²⁹ and increased prevalence of Heberden nodes.³⁰ The elongated tibial spines common in obesity-related knee osteoarthritis are ossifications of the enthesal attachments of the cruciate ligaments.¹⁴

INVESTIGATIONS

DISH cannot be diagnosed without radiologic evaluation. Although DISH is often first identified on a routine posteroanterior chest radiographic

Fig. 182.2 Hand of a patient with diffuse idiopathic skeletal hyperostosis demonstrates the full spectrum of bone and enthesal changes in this disorder. Note prominent phalangeal enthesopathy (second and third proximal phalanges), "arrowheading" (tufts of terminal digits), exostoses (second and fifth metacarpophalangeal heads), capsule bone (fourth proximal phalangeal joint), cortical thickening (tubular bones), and enlargement of sesamoid bones. The soft tissues and joint spaces are normal.¹⁵

projection (Fig. 182.3), the appropriate studies are posteroanterior and lateral views of the thoracic or dorsal spine.³¹ Computed tomography (CT) provides more dramatic images (Fig. 182.4) but is not necessary unless the presence of conditions such as spinal stenosis is being sought. Magnetic resonance imaging (MRI) shows the ligamentous thickening that precedes ossification. Plain radiographs of peripheral areas show variable degrees of peripheral enthesopathy (see Fig. 182.2). Bone scans show no change in the involved area but may help identify an associated process such as spinal fracture or mechanically induced inflammatory enthesal changes.

Routine biochemical findings and erythrocyte sedimentation rate are normal. There are often abnormalities associated with hyperinsulinemia, non-insulin dependent diabetes, dyslipidemia, gout, and metabolic syndrome.³²⁻³⁴

DIFFERENTIAL DIAGNOSIS

One of the most important differential diagnoses is that of ankylosing spondylitis. The new bone formation in DISH may be smooth and tightly fused to the underlying cortex, thus mimicking ankylosing spondylitis. Usually, however, exuberant and bumpy bony change within the anterior longitudinal ligament, with preservation of the original cortex, is characteristic of DISH. The diagnostic problem is occasionally compounded by anterior osteophytosis of the sacroiliac joints, which may lead to a change falsely interpreted on plain radiographs in posteroanterior view as postinflammatory fusion of the joints. In this situation, CT of the sacroiliac joints shows the anterior fusion with no inflammatory change in the joint itself, and MRI confirms lack of any inflammation-related bone edema.

Degenerative disk disease characteristically results in disk space narrowing with horizontal osteophytes, prominent anteriorly. Facet joint hypertrophic changes are commonly seen and narrow the intervertebral neural foramina as well as the spinal canal. The hyperostotic peripheral joint changes of DISH resemble primary osteoarthritis in distribution but are distinguished by early stiffening and relative preservation of joint space in the early stages.^{15,22}

Acromegaly is also characterized by new bone formation, but subcutaneous soft tissue and cartilage thickening are prominent. In early acromegaly there is hypermobility, in striking contrast to the stiffening characteristic of DISH. The bony spurs and hyperostosis of DISH may at times be identical to those seen in acromegaly, and both conditions are associated with hyperostosis frontalis interna.³⁵ There is no increase in joint space or in soft tissue thickness in DISH.¹⁵ Repetitive trauma, fluorosis, hypervitaminosis A, and

Fig. 182.3 Typical radiographic findings in the thoracic spine on routine chest radiographs in posteroanterior (a) and lateral (b) views, with “flowing” new bone formation linking four contiguous vertebrae, predominantly right-sided, in the absence of intervertebral disk change.

Fig. 182.4 Computed tomographic reconstruction of the thoracic spine of a patient with diffuse idiopathic skeletal hyperostosis. There is prominent new bone deposition on the right anterolateral thoracic spine.

retinoid therapy may all produce enthesopathy, which may require differentiation from DISH.

ETIOLOGY AND PATHOGENESIS

The principal changes in DISH occur at the enthesis. Chondrocytes lying in the enthesal region bordering the bony interface are activated and cause

changes to the surrounding matrix that favors subsequent ossification (Fig. 182.5). Later, vascular invasion occurs from the adjacent cortical haversian canals and preferential ossification occurs at, or close to, the enthesis (Fig. 182.6).^{4,36} The resultant enthesal bone deposition is further modified by local mechanical factors.

The propensity to deposit new bone has an underlying metabolic cause. Since the early reports of Forestier, an association between obesity and DISH has been noted.¹ Subsequently a link was observed with impaired glucose tolerance and related adult-onset type 2 diabetes.^{32,37} The prevalence of these abnormalities in patients with DISH ranges from 17% to 60% and thus is much higher than in the general population. Conversely, the prevalence of DISH in patients with adult-onset type 2 diabetes ranges from 13% to 50%. Glucose intolerance and obesity seem to act as independent factors in their association with DISH, although there is no relationship between the degree of hyperglycemia and the severity of the bony change. No patients with type 1 or insulin-deficient diabetes have been found to have DISH.

Levels of candidate bone growth factors such as growth hormone and somatomedin (insulin-like growth factor) are not consistently abnormal in DISH. In contrast, levels of insulin, which also has growth factor activity, have been found to be significantly higher in individuals with DISH (Fig. 182.7).^{37,38} Hyperinsulinemia is seen in Pima Indians, who have a high prevalence of DISH,⁸ and it is also associated with hyperostosis frontalis interna and ossification of the posterior ligament (OPLL) (Fig. 182.8).³⁹ Insulin promotes endochondral ossification by enthesal chondrocytes.⁴⁰ The hyperinsulinemia likely relates to the documented association among DISH, central obesity, hypertension, lipid abnormalities, and increased risk of vascular disease,⁴¹ all of which are components of metabolic syndrome.³³

OPLL, more common in Japan, shares many features with DISH but is present predominantly in the cervical spine. Patients with OPLL also have increased rates of type 2 diabetes, and in addition, involvement of bone growth factors such as bone morphogenic proteins and transforming growth factor- β has been demonstrated in various histochemical and cytochemical analyses.⁴²

Dickkopf-1 (Dkk-1) is an inhibitor of osteoblastogenesis and low levels link with new bone formation. One study found Dkk-1 levels to be low in DISH,⁴³ although another study did not confirm this observation.⁴⁴

Fig. 182.5 Histopathologic (a) and radiologic (b) changes in an intervertebral disk in a patient with diffuse idiopathic skeletal hyperostosis.

Fig. 182.6 Progressive spinal enthesal changes in diffuse idiopathic skeletal hyperostosis (DISH). The earliest change is shown in (a), with ossification at the site of attachment of the anterior longitudinal ligament to the middle of the vertebral body, well away from the annulus. Note the separation of the ossification from the intact cortex, except at the site of attachment. Moderate changes are seen in (b), with ossification bridging the disk space but still firmly attached to cortex at the middle of the vertebral body. Advanced changes, typical of established DISH, are shown in (c), with smooth attachment of the new bone to the original cortex. The ossified ligament is much thickened and interrupted at the lower level.

Chronic vitamin A toxicity in animals and humans produces DISH-like changes. Studies of vitamin A and metabolites in stimulated states indicate an increased level of these retinoids in patients with DISH,⁴⁵ but the significance of this remains speculative.

Familial clustering^{46,47} and association with the *COL6A1* gene in some populations⁴⁸ suggest that genetic factors are also likely to be involved in DISH.

MANAGEMENT

Prevention

A high risk of DISH may be anticipated in large-boned, large-muscled individuals with abdominal obesity and metabolic syndrome. Thus patients

with gout, hypertension, and peripheral enthesopathies and stiffness of the hips and shoulders or large, stiff fingers may have this disorder. Abnormal lipids characteristic of metabolic syndrome and abnormal glucose metabolism including hyperinsulinemia may be found. The best therapy at this stage is weight reduction, ideally through a fitness program (Table 182.2).

Specific interventions

There is no specific treatment available for established DISH. However, patients should be carefully assessed and treated for components of metabolic syndrome, namely, diabetes, dyslipidemia, gout, and hypertension.

Physical therapy may benefit patients with stiffened spinal regions and help relieve symptoms in peripheral joint areas, although no confirmatory published literature is available.

Fig. 182.7 Hyperinsulinemia during a standard glucose tolerance test in nondiabetic individuals with diffuse idiopathic skeletal hyperostosis (DISH), compared with control subjects matched for age, gender, and body mass index.⁴² Values are mean $\pm$ standard error in pmol/L.

TABLE 182.2
Management issues in diffuse idiopathic skeletal hyperostosis

Issue	Management
Spinal and peripheral enthesopathy	
Asymptomatic (usual)	Encourage exercise and ideal body weight, assess cardiovascular risk factors
Symptomatic	As above; plus physical therapy, local injection therapy, use of analgesic/antiinflammatory agents
Complications	
Facet arthritis	Physical therapy, injection
Spinal stenosis	Exercise, injection, surgery
Dysphagia	Conservative management, surgery
Osteoarthritis	Standard approaches
Associated metabolic syndrome	
Hypertension, diabetes, dyslipidemia, gout, obesity	Treat vigorously

Fig. 182.8 Magnetic resonance image of the cervical spine of a 58-year-old white male with concurrent diffuse idiopathic skeletal hyperostosis and ossification of the posterior ligament, with the latter causing symptomatic cervical cord compression.

Surgical interventions may rarely be necessary for complications such as osteophytic dysphagia or spinal stenosis.

Peripheral enthesal pain, usually induced by microtrauma, may be helped by the use of orthotics, physical therapy, or carefully placed local anesthetic and corticosteroid injections.

Peripheral osteoarthropathy may be preceded by asymmetric acceleration of capsular thickening and new bone formation around the joint, with stiffening further increasing the crushing forces through the joint. Anecdotally, local cortisone injections may improve range of motion and relieve pain.

The risk of heterotopic bone formation following hip arthroplasty may be reduced by administration of nonsteroidal antiinflammatory medications, although this complication is uncommon.⁴⁹

Neuropathic arthropathy

■ DIMITRIOS G. KASSIMOS ■ LOUKIA A. KOUTSOGEORGOPOULOU ■ PAUL CREAMER

- Neuropathic arthropathy is a progressive, destructive joint disease associated with sensory loss.
- It is characterized by relative lack of pain resulting from sensory neuropathy, and by atrophic changes on plain radiography.
- Bony swelling and soft tissue enlargement, effusion, laxity, instability, and deformity occur.
- Common sites of joint involvement are the midfoot, ankle, and knee, and less commonly, the hip, spine, shoulder, and wrist.
- Joint destruction, subluxation, heterotopic new bone formation, and recurrent or persistent joint effusion are involved.

HISTORY

Neuropathic arthropathy is a relatively painless, progressive, destructive arthropathy caused by a neurologic deficit. The first description was probably by William Musgrave (1655-1721), a physician from the West of England, but it was the French neurologist Jean-Martin Charcot (1825-1893)¹ who gave his name to the condition. In 1868 he described “l’arthropathie des ataxiques” in a French soldier with tertiary syphilis who had been marching 25 km each day. He thought that the “bag of bones” represented spontaneous fractures as a result of nerve degeneration and bone atrophy. Sir James Paget named the condition after Charcot in 1881, but in this chapter the term *neuropathic arthropathy* is used throughout. In 1917 Eloesser assessed the role of trauma in the development of neuropathic arthropathy by cutting the posterior roots of the spinal cord in cats, which resulted in analgesia, anesthesia, and ataxia. His work was used to support the neurotraumatic theory of pathogenesis. In 1936 Jordan² gave the initial description of neuropathic arthropathy associated with diabetes. Diabetes is now the most common cause of neuropathic arthropathy, accounting for two thirds of all cases in the lower limb.³ Leprosy⁴ is a common cause in endemic areas of the disease.

Neuropathic arthropathy can complicate a variety of sensory neurologic disorders. In addition to tabes dorsalis (syphilis), diabetes, and leprosy, has been described in syringomyelia,⁵ multiple sclerosis, amyloidosis, congenital insensitivity to pain,⁶ spinal cord trauma⁷ and tumors, arachnoiditis after spinal anesthesia or meningitis, familial dysautonomia (Riley-Day syndrome), familial and other polyneuropathies,⁸ peroneal muscular atrophy, and neurofibromatosis.⁹ In childhood the most common cause is spina bifida with meningocele. Neuropathic arthropathy has been described secondary to the neuropathy of human immunodeficiency virus (HIV) infection¹⁰ (which may be exacerbated by the use of nucleoside reverse transcriptase inhibitors); the success of highly active antiretroviral therapy means that prolonged life span may result in more HIV-associated neuropathic arthropathy in the future. In up to 30% cases of neuropathic arthropathy, no apparent neurologic disorder is found.

ETIOLOGY

Diabetes mellitus

Sensory neuropathy is a complication seen in up to 60% of individuals with diabetes mellitus, especially if it is long-standing or poorly controlled. Neuropathic arthropathy occurs in 0.1% to 0.5% of diabetic patients, with an

approximately equal sex ratio.³ Typically patients have severe distal symmetric neuropathy, are 50 to 60 years old, and have at least a 10-year history of diabetes.¹¹ Neuropathic arthropathy in diabetes is frequently associated with ulcers and ischemic lesions in the feet, as well as other evidence of microangiopathy.

Syringomyelia

An estimated 20% to 25% of patients with syringomyelia develop neuropathic arthropathy.⁵ It is usually monoarticular and typically affects joints of the upper extremity, especially the glenohumeral joint¹² (Fig. 183.1), elbow, wrist (Fig. 183.2a and b), or fingers. Bilateral and symmetric involvement is less frequent in syringomyelia than in tabes dorsalis. Neurologic manifestations due to spinal cord damage include loss of pain and temperature sensation, although tactile and postural sensitivity is preserved; wasting of the intrinsic muscles of the hand (see Fig. 183.2c); and amyotrophic paralysis in the upper limb. Magnetic resonance imaging (MRI) (Fig. 183.3) can demonstrate spinal cord enlargement,¹³ especially in the cervical region.

Tabes dorsalis

Of patients with tertiary syphilis, 5% to 10% develop neuropathic arthropathy.¹⁴ It is still the classic model for neuropathic joint disease despite its decreasing incidence.¹⁵ Both sexes are affected equally. The onset is usually in adulthood. The lower limb joints are affected in 60% to 75% of cases, with involvement of knee, hip, ankle, shoulder, and elbow in descending order of frequency (Fig. 183.4). Other joints involved are the forefoot, midfoot, vertebral column, and sternoclavicular joints. Monoarticular involvement predominates but is not universal. Diagnosis requires identification of specific antitreponemal antibodies in blood and cerebrospinal fluid.

Leprosy

Leprotic patients develop peripheral neuropathy with a variety of secondary changes in the feet. Neuropathic arthropathy can result from long-standing neuropathy, with little evidence of active leprosy.⁴ The disease alters the shape of the hands and feet owing to subluxation of individual joints. In the feet the changes usually start in the medial arch and later involve the lateral arch, talus, and calcaneus. In extreme cases, dissolution of the midfoot results in separation of the forefoot and the hindfoot, and the tibia is driven downward to become weight bearing. The pathogenesis in this type seems to be mainly direct trauma to the forefoot.

Congenital indifference to pain

Another group of disorders that can lead to neuropathic arthropathy includes congenital insensitivity to pain and hereditary sensory neuropathies types I to IV. The pathogenesis appears to be the same as that in other causes of neuropathic arthropathy. Often, there is marked disproportion between the severity of the disease process and clinical symptoms.⁶

Meningomyelocele (spinal dysraphism)

Neuropathic changes in childhood raise the possibility of congenital indifference to pain or meningocele. Principally the ankle and tarsal articulations are affected. In active children changes may appear in the first 3 years of life and include osteoporosis, diaphyseal and metaphyseal fractures, injuries of the growth plate, epiphyseal separations, persistent effusions, articular destruction, and soft tissue ulcerations.

CLINICAL FEATURES

The distribution of joint involvement depends on the underlying neuropathy (Table 183.1). Monoarticular or oligoarticular involvement is most common, but polyarticular forms do occur.

Early neuropathic arthropathy is characterized by an acute inflammatory phase with erythema, warmth, swelling, and edema.¹⁶ Pain may be present despite sensory neuropathy. Pedal pulses are typically easily palpable, and a temperature gradient of 2° to 5° C between the affected and contralateral foot might be noted. There may be a history of trauma. Radiographic findings may be normal at this stage,¹⁷ but MRI scans may suggest neuropathic arthropathy.¹⁸ The differential diagnosis includes infection, sprain, and cellulitis (see also later). Correct diagnosis is vital, because delay and continued weight bearing leads to increased bone destruction and major deformities. Untreated, the disease progresses to chronic neuropathic arthropathy.

In diabetes the midtarsal joint is most commonly affected, which results in midfoot collapse and a valgus forefoot. The hindfoot may also be affected, and pathologic fracture of the fibula can occur. Tarsometatarsal joint

involvement is associated with edema of the dorsum of the foot and bony deformities, with dorsal prominence or plantar protrusion. On examination, the range of motion is usually subnormal but may even be excessive as a result of laxity and subluxation (Figs. 183.5 and 183.6). Instability becomes permanent and deteriorates with time. Downward collapse of the tarsal bones may produce abnormal convexity of the plantar surface, with the end result being a rigid rocker-bottom foot. Trophic skin lesions and ulcers frequently accompany the articular disorder on the sole of the foot.

Neuropathic arthropathy at the knee is usually of gradual onset, although it may be subacute or even acute, occurring within a few hours (pseudoinflammatory). The knee becomes warm and swollen, with signs of joint effusion. Patients may delay seeking medical opinion until the knee has become permanently swollen, with instability leading to valgus, varus, or recurvatum deformities, and enlargement of the articular bones and periarticular tissues. Despite gross abnormalities the patient may be able to walk, albeit with a limp.

A similar clinical picture is seen in other major limb joints. When the hip is affected (Fig. 183.7) there is often extensive joint destruction, shortening of the leg, severe loss of function, and a limp. The hand is rarely involved, and the manifestations in general are less severe. They include vasomotor problems, digital ulcers, thickening of the fingers, and painless subluxation of the finger joints. In the spine localization is most frequent in the lumbar region, although the cervical and dorsal spine may also be involved. Severe deformity (kyphosis, scoliosis) may result despite normal mobility and relative absence of pain. Because of this paucity of symptoms, the condition is often first discovered during routine examination. Occasionally, signs of nerve root compression are present.

The belief that neuropathic joints are painless is probably untrue. Arthralgia is well documented in up to 50% of patients, although the symptoms are usually less than expected from the degree of joint destruction.

Fig. 183.4 Syphilitic Charcot knee joints showing gross destructive changes.

IMAGING

Plain radiography

In the early stages, radiographs may show normal findings or reveal only soft tissue swelling. Other early features include periosteal calcification and joint effusion. The presence of an enlarging and persistent effusion, minimal subluxation, fracture, and fragmentation suggests the possibility of neuropathic arthropathy. After a few weeks the calcification becomes more dense and the bone margin less well defined.^{16,17}

Radiographs in established neuropathic arthropathy (Fig. 183.8) show a disorganized joint characterized by bone resorption and formation occurring simultaneously. Fractures may occur, and free fragments of bone may be seen in the joint cavity. The degree of sclerosis, osteophytosis, and fragmentation is greater than in other articular diseases. The bone fragments and irregular articular surfaces resulting from the osseous destruction are generally well defined and sharp; poorly margined, ill-defined bone contours, as occur in septic arthritis, are not evident unless there is additional infection (not infrequent, especially in diabetic patients). Intraarticular bony

Fig. 183.5 Diabetic neuropathy of the hindfoot. Destruction of the joint with collapse and fragmentation is seen.

Fig. 183.6 Neuropathic ankle. Marked instability of the subtalar and midtarsal joints is seen with collapse on weight bearing.

Fig. 183.7 Neuropathic hip secondary to tabes dorsalis. (Courtesy Dr. I. Watt.)

Fig. 183.8 Neuropathic disease of the left knee (tabes dorsalis). (a) Advanced form of the disease in the knee. (b) The same knee 13 years previously showing partial fracture of the tibial epiphysis.

fusion is an uncommon manifestation of neuroarthropathy at any site, with the exception of the spine (Fig. 183.9).¹⁷

Progression from the early stage can be rapid, which suggests that microfractures evolve quickly into gross fragmentation, with complete destruction of the articulation within a few weeks.

Other imaging techniques

Bone scintigraphy (late phase) can be useful for assessment of bone turnover, evaluation of disease progression, and monitoring of activity.¹⁹ MRI is more sensitive than radiography¹⁸; the primary early abnormality is

extensive bone marrow edema. Although there are other potential causes for this, including infection, joint trauma, seronegative arthritis, complex regional pain syndrome (CRPS) and transient bone marrow edema, early neuropathic arthropathy can be differentiated from these various other conditions on the basis of the clinical history and presence of peripheral neuropathy. Given the importance of early diagnosis in preventing chronic neuropathic arthropathy, early use of MRI has a valuable role (Fig. 183.10).

MRI also allows the extent of the soft tissue lesions to be defined and may be of value in the differentiation of neuropathic arthropathy from infection, a distinction that can be difficult to make, especially when neuropathic arthropathy is complicated by adjacent loss of skin integrity. Of course both may coexist, especially in the diabetic foot.²⁰ Infection results in high signal on T2 weighting and short tau inversion recovery and low signal on T1 weighting. Acute neuropathic arthropathy is similar, but chronic neuropathic arthropathy has normal marrow signal or low signal on T1 and T2 weighting. Other features that may help differentiate neuropathic arthropathy include distribution, deformity, and soft tissue changes. Positron emission tomography–computed tomography (PET-CT), if available, may also be useful for differentiating neuropathic arthropathy from osteomyelitis. The sensitivity of PET-CT in this situation has been reported as 100% and its specificity as 93.8%.²¹ Areas of low signal intensity on MRI have been reported in the medullary cavity of the bone on both T1- and T2-weighted spin echo images in syringomyelia (see Fig. 183.3) even before the actual resorptive process occurs.²²

LABORATORY INVESTIGATIONS AND HISTOLOGIC ANALYSIS

The synovial fluid may be serous, serosanguineous, or frankly hemorrhagic, and lipid crystals secondary to subchondral bone lesions may be seen. Bone biopsy may sometimes be useful to exclude other diagnoses such as osteosarcoma, metastatic carcinoma, or osteomyelitis. The most common histologic findings are fibrosis with cartilaginous and bony metaplasia and embedded fragments of necrotic or viable bone (detritic synovitis). Necrotic and reactive cartilage and rice body–like articular fibrinous material have also been described in the joint. Laboratory evidence of an acute-phase response or systemic disturbance is lacking.

DIFFERENTIAL DIAGNOSIS

Typical presentation is a swollen joint with mild discomfort in a patient with known neuropathy. The combination of marked clinical manifestations in the presence of relative lack of pain and good functional capacity, together

Fig. 183.10 Magnetic resonance images of the hindfoot in a patient with neuropathic arthropathy. (a) T1-weighted sagittal image. (b) Short tau inversion recovery sagittal image. There is extensive bone marrow edema around the subtalar and calcaneocuboid joint with soft tissue edema anterosuperior to the midfoot. Erosion is seen at the anterosuperior margin of the talus with some destruction of the navicular. Note evidence of previous surgical ankle fusion.

with a typical radiographic picture, suggests the diagnosis. If a neurologic disorder is not readily apparent or if the clinical or radiographic appearances are unusual, then the diagnosis may be more difficult, especially in early disease. Differential diagnoses include infection (joint or bone); crystal disease (gout, calcium pyrophosphate deposition disease, or hydroxyapatite arthropathy); other inflammatory arthritis including rheumatoid arthritis²³; tumor; and thrombophlebitis. Bony fragmentation and collapse are also manifestations of osteonecrosis. Similar appearances have been reported in posttraumatic osteoarthritis (OA) and after repeated intraarticular corticosteroid injections.

A careful neurologic examination should be carried out because this should identify a sensory neuropathy. In practice, the most important differential diagnosis is septic arthritis, and if there is any clinical doubt one should aspirate the involved joint and send synovial fluid for microscopic analysis and culture. An algorithmic approach to distinguishing neuropathic arthropathy of the foot from osteomyelitis has been proposed.²⁴

PATHOGENESIS

The pathogenesis of neuropathic arthropathy remains controversial.²⁵ Although sensory impairment, overuse, and trauma are recognized as predisposing factors, these are neither necessary nor sufficient to account for the observed clinical and pathologic features.

Any theory of pathogenesis must take account of those features that distinguish neuropathic arthropathy from other forms of destructive arthritis. These include peripheral neuropathy, abnormal biomechanics, and marked destructive changes with fracture and loss of bone. It must also explain asymmetry, relative rarity (only a small minority of patients with sensory neuropathy develop neuropathic arthropathy), and the fact that chances of developing neuropathic arthropathy do not appear to relate to either the severity of neuropathy or the degree of physical activity.²⁶ Finally, a satisfactory theory should explain why the condition is self-limiting.

Traditionally, two theories have been proposed. The first, the “neurotraumatic” theory, suggests that somatic muscular reflexes that normally protect the joint from exceeding certain safe limits in range of movement are lost in the presence of neuropathy, which leads to repeated trauma and ultimately joint destruction. Volkmann and Virchow described the changes as resulting from “a multiplicity of subclinical traumas, which are unperceived because of the insensitivity of the affected joints.”²⁷

The second, or “neurovascular,” theory holds that neuropathic arthropathy develops as a result of increased blood flow, with the relative hyperemia resulting in active resorption of bone. There is good evidence that blood flow is increased in peripheral neuropathy, due to loss of sympathetic innervation and reduced peripheral vascular resistance.²⁶ Also, cases have been described in which neuropathic arthropathy developed in patients with diabetes only after reconstructive vascular surgery.²⁸ A potential problem with this theory is that autonomic neuropathy, suggested as a major determinant of neuropathic arthropathy, is not invariably present in conditions such as leprosy or hereditary sensory neuropathies, which nevertheless cause neuropathic arthropathy.

Both these theories presuppose that sensory nerves actively prevent development of neuropathic arthropathy in normal joints, and disruption of these nerves should lead inevitably to a neuropathic joint. In fact, it is clear that even extensive deafferentation of a joint does not necessarily lead to pathologic joint processes in the absence of trauma or infection. Attempts to create neuropathic arthropathy in cats, rabbits, and dogs have met with limited success. In the canine anterior cruciate ligament (ACL) transection model of OA, ACL transection inevitably led to OA in active dogs, but

denervation at the dorsal root ganglion alone did not lead to OA or neuropathic arthropathy even if the dogs were allowed to remain active.²⁹ However, the combination of ACL transection and denervation led to more severe OA than ACL transection alone.³⁰

These experiments refute the theory that neuropathic joints result from a peripheral sensory neuropathy in the presence of normal activity, although they would explain the development of joint destruction in the presence of neuropathy and joint instability.

Recently an attempt to link these findings has been made by suggesting a role for inflammation and, in particular, proinflammatory cytokines.²⁶ Inflammation is undoubtedly a key feature of neuropathic arthropathy and may result from microtrauma or fracture, although a role has also been suggested for ulceration, infection, and local surgery, including orthopedic procedures³¹ or revascularization.²⁸ The acute inflammatory response triggers expression of the receptor activator of nuclear factor- κ B ligand (RANKL) and, hence, activation of nuclear factor- κ B (NF- κ B). In turn, this causes activation of osteoclasts and increased bone resorption, which leads to further fracture and potentiation of the inflammatory cycle.

Stimulation of the RANKL–NF- κ B axis is part of the normal response to fracture, allowing lysis of bone fragments before new bone formation. Normally, however, the process is switched off, perhaps by pain and immobilization. Loss of the normal pain response in neuropathic arthropathy may cause the lytic process to continue. It is also possible that the RANKL system may be primed in diabetes³² because it is potentiated by free radicals and hyperglycemia. Neuropathy itself may further activate the system due to loss of neurally derived antagonists of RANKL such as calcitonin gene-related peptide. This downregulation of inhibitor nerve pathway (loss of sensory neuropeptide and cholinergic antiinflammatory pathway) may be one cause of the exaggerated inflammatory response to minor trauma.³³

Clearly such a hypothesis has implications for clinical practice. Inhibitors of inflammation such as high-dose steroids or tumor necrosis factor (TNF) antagonists may break the vicious cycle, although benefit would have to be weighed against risk—especially risk of infection.

MANAGEMENT

The treatment of the neuropathic joint depends on the joint involved and the stage of disease. Despite progress in our understanding of the disease, curative treatment of established neuropathic arthropathy remains impossible. Treatment of the neurologic disorder, such as surgical repair of syringomyelia, is indicated when possible but will not reverse established arthropathy. Management is further hampered by a paucity of randomized controlled trials and by the lack of consensus on disease definition. There is agreement that the key to successful conservative treatment is early recognition to prevent joint destruction.³⁴

Acute neuropathic arthritis

The aims of early treatment are to arrest the acute process and prevent deformity. Early early diagnosis is vital in this regard, which makes the early stages of neuropathic arthropathy a true medical emergency.

Reduction of weight bearing

Immobilization of the joint and, in cases of lower limb involvement, cessation of weight bearing are important during periods of apparent flare in activity. Joint immobilization with a plaster cast may be required for up to 6 months, with the aim of stabilizing the joint and improving the osteoarthritic lesion. Such prolonged periods of immobilization require clear

explanation to the patient, especially because the patient may be relatively asymptomatic at the time. Orthotic devices are used as required to permit limited mobilization. A balance has to be struck between restricting mobility and allowing a return to weight-bearing ambulation, and some studies suggest that, if immobilization is good, weight bearing can be permitted without detriment.³⁵ Recently pneumatic walking braces have been introduced for ankle and foot arthritis, which reduce weight bearing but are comfortable, lightweight, and removable at night.³⁶

Bisphosphonates

Because excess osteoclastic activity is thought to be responsible for the bone destruction in neuropathic joint disease, therapies that inhibit osteoclasts, such as bisphosphonates, may be helpful, especially if given early. A 12-month randomized, double-blind, placebo-controlled trial of a single intravenous infusion of pamidronate 90 mg or placebo in 39 patients with diabetic neuropathic arthropathy showed greater improvement in symptoms, markers of bone turnover, and skin temperature in treated patients at 1 year.³⁷ A retrospective study (n = 23) of neuropathic arthropathy affecting the feet compared intravenous pamidronate with traditional immobilization techniques and found a significant reduction in temperature and bone turnover as judged by alkaline phosphatase activity.³⁸ However, a recent study found no benefit of intravenous zoledronic acid on the clinical resolution of acute neuroarthropathy in terms of total immobilization time.³⁹

Other treatments that have been used in the acute stage include low-intensity ultrasound, magnetic fields, and nonsteroidal antiinflammatory drugs (NSAIDs) to control pain, but there is no evidence of an effect on progression.

Chronic neuropathic arthropathy

Once chronic neuropathic arthropathy is established in the foot, the goals of treatment are primarily to reduce the risk of foot ulceration. Reduction of plantar pressure, preservation of skin integrity, and support for the foot are important aims. Input from an expert orthotist is vital; provision of a good foot orthosis or rocker soles in adapted footwear may be all that is required.

Neuropathic arthropathy elsewhere is treated following similar principles: supports, splinting, orthosis, and preservation of skin integrity. Pain needs to be managed with analgesics or NSAIDs. Ulcers require rigorous hygiene: disinfection, sterile bandaging, and antibiotic treatment of any superimposed infection.

Surgery is best avoided if possible due to the risk of worsening of the condition, nonunion, infection, and precipitation of acute neuropathic arthropathy in the contralateral limb. Sometimes simple excision of abnormally weight-bearing bone may be all that is required,³¹ but for marked instability or a fixed deformity open reduction and arthrodesis may be indicated. Other indications for surgery include ulceration and unacceptable deformity, because these increase the risk of further bony breakdown. Surgical options vary by site. At the knee arthrodesis is the preferred option. The risk of nonunion may be reduced by use of careful technique; firm fixation of the bones with an intramedullary rod or other device; and débridement of all synovial tissue and scarred capsule. Neuropathic knees⁴⁰ and hips⁴¹ can be treated by total joint arthroplasty, although this can be challenging technically and the rate of reoperation is high.

Surgical algorithms for the treatment of neuropathic arthropathy of the foot are based almost entirely on level 4 or 5 evidence. Uncontrolled retrospective case series and case reports guide the use of exostectomy, fusion, and Achilles tendon lengthening. There is inconclusive evidence concerning timing of treatment and use of different fixation methods.⁴²

Unfortunately, the combination of marked joint destruction and, not infrequently, superimposed infection can make amputation the only viable option.

CONCLUSION

Apart from an association with diabetes, neuropathic arthropathy is a rare condition. It is important to consider, however, because early recognition and treatment may significantly alter the prognosis. It enters the differential diagnosis of monoarthritis and, in an appropriate clinical setting, should prompt a careful neurologic examination.

The mechanism by which sensory changes result in such gross destructive arthritis is unclear but may relate to production of cytokines consequent to low-grade trauma and inflammation. The disease bears a marked resemblance to certain forms of atrophic OA; this, combined with recent animal experiments, raises the intriguing possibility that neurologic factors may play a role in OA. Future targets for research might include further evaluation of the role of bisphosphonates in acute neuropathic arthropathy and the effect of targeting inflammation by the use of either nonspecific inhibitors such as steroids or specific antagonists of, for example, TNF- α or RANKL (such as denosumab). The rarity of the condition makes it an ideal subject for international collaborative research.⁴³

184 Osteonecrosis

■ TIMOTHY McALINDON ■ ROBERT J. WARD

- Osteonecrosis is cell death in components of bone: hematopoietic fat marrow and mineralized tissue.
- Osteonecrosis is not a specific disease entity. It is the final common pathway of a number of conditions, most of which lead to impairment of the blood supply to the femoral head; this explains the frequently used terms *avascular necrosis* and *aseptic necrosis*.
- The femoral head is the site most commonly and severely affected by osteonecrosis. However, osteonecrosis may also develop in other locations (including the distal femur, humeral head, and small bones of the wrist and foot).
- Radiologic changes are typical at the late stages of the disease, but radiographic findings can be normal at early stages. Magnetic resonance imaging is especially useful in these stages.
- Predisposing factors (mainly corticosteroid use and alcohol abuse) should be carefully sought.

INTRODUCTION

Osteonecrosis refers to a clinical syndrome in which regional death of the cellular elements of bone, typically in a subchondral location, leads to trabecular and subchondral collapse with consequent pain, impairment, and long-term joint damage. Osteonecrosis can occur in a variety of clinical settings and skeletal sites, with or without apparent predisposing factors. Although a number of synonyms have historically been used to refer to this disorder (such as *aseptic necrosis* and *avascular necrosis*), the commonalities among these suggest that osteonecrosis is the endpoint of a number of conditions that impair blood supply to regions of bone. However, within the clinical spectrum of osteonecrosis, there exist distinct subsets with unique features that suggest rather specific causes (e.g., bisphosphonate-associated osteonecrosis of the jaw, transient osteoporosis of the hip in pregnancy, and spontaneous osteonecrosis of the knee). The condition is of clinical importance because there is often a lag in diagnosis, and early intervention may be necessary.

EPIDEMIOLOGY

The true incidence and prevalence of osteonecrosis are unknown. The most reliable data relate to the hip joint and are inferred from the number of hip arthroplasties performed each year for this specific indication. Recent estimates suggest that osteonecrosis accounts for up to 10% of hip arthroplasties.¹ From this it is assumed that there are approximately 10,000 to 20,000 new cases of osteonecrosis diagnosed each year in the United States.² The condition affects both genders and all age groups but with a substantially greater prevalence among males.³ Patients with osteonecrosis tend to be younger than 50 years of age³; however, the demographic characteristics of patients with osteonecrosis vary for the different subtypes.

Osteonecrosis is associated with a variety of clinical conditions such as systemic lupus erythematosus (SLE) and chemical exposures such as corticosteroid and alcohol use (Box 184.1).⁴ Indeed, recent epidemiologic studies have tended to focus on specific subsets or exposures such as

osteonecrosis associated with renal transplantation or intravenous administration of zoledronic acid.⁵ The factors that have received the most scrutiny include corticosteroid exposure, alcohol use, SLE, coagulopathies, and hemoglobinopathies, and bisphosphonate use.⁴

Corticosteroids

Accumulated data from numerous clinical reports and risk factor studies provide strong evidence for a causal relationship between corticosteroid exposure and development of osteonecrosis. The incidence (or cumulative prevalence) rates of osteonecrosis among different cohorts exposed to corticosteroids range from 0.6% to 38%, presumably because of widely varying exposures and host factors. Although there is a general trend in the more systematic analyses toward increased risk of osteonecrosis with greater dose and longer duration of use of corticosteroids,⁴ the identification of individuals at particular risk from corticosteroid exposure is clearly difficult.

Alcohol

Alcohol consumption is also considered to be an established risk factor for osteonecrosis. One case-control study demonstrated a dose-response relationship for alcohol in osteonecrosis, with risk ratios of 3, 10, and 18 for those regularly consuming less than 400, 400 to 1000, and 1000 mL/wk or more, respectively, compared with nondrinkers.⁶ One theory suggests that altered fat metabolism secondary to alcohol use may lead to adipocyte hypertrophy and subsequent microvascular compression with resulting increased intraosseous pressure.⁷ Recently it has also been determined that both alcohol and corticosteroids have adverse effects on bone cell lineage by enhancing adipogenesis and inhibiting osteocytogenesis by marrow stem cells.⁸ Other studies point toward direct cytotoxic effects of alcohol.⁹ Interestingly, there appear to be differences in the frequencies of alcohol-metabolizing enzyme gene polymorphisms among subpopulations of patients classified as having alcohol-related osteonecrosis.¹⁰

Systemic lupus erythematosus

Osteonecrosis occurs frequently in SLE, with clinically apparent disease in up to 15% of patients and even higher prevalence when asymptomatic disease is detected using magnetic resonance imaging (MRI). Much of this risk is related to corticosteroid treatment. However, attempts to determine which patient characteristics mediate this risk have produced inconsistent results.¹¹⁻¹⁴ It is likely that multiple factors in patients with SLE interact with or contribute to the development of osteonecrosis, including procoagulant factors such as anticardiolipin antibodies.¹⁵

Coagulopathies and hemoglobinopathies

Osteonecrosis appears to be associated with a range of coagulation disorders and with hemoglobinopathies, most notably sickle cell disease and sickle cell-hemoglobin C (hemoglobin SC) disease. Among patients with sickle cell disease the prevalence of symptomatic osteonecrosis is 3% to 5% and rises to 10% to 41% when asymptomatic osteonecrosis is included.^{16,17} In sickle cell disease, the risk of osteonecrosis is related to measures of the disease process including frequency of crises, hematocrit levels, and mean corpuscular volume.¹⁶ These clinical observations suggest that thrombosis and vasoocclusion participate in the development of osteonecrosis. Studies of hypofibrinolysis and thrombophilia in osteonecrosis have found increased plasminogen activator inhibitor activity and polymorphism of the plasminogen activator inhibitor-1 gene in certain patients.^{15,18-20}

BOX 184.1 EXPOSURES AND MEDICAL CONDITIONS ASSOCIATED WITH OSTEONECROSIS

Trauma	Slipped capital femoral epiphysis
Dysbaric osteonecrosis	Systemic lupus erythematosus

Corticosteroid use	Hemophilic disorders
Alcohol use	Hemoglobinopathy
Bisphosphonate use	Pregnancy
Hyperlipidemia	Gaucher disease
Legg-Calvé-Perthes disease	Human immunodeficiency virus
Congenital dysplasia of the hip	infection

Bisphosphonate-induced osteonecrosis of the jaw

Bisphosphonates are the mainstay for treatment of osteoporosis. In 2003 the first report of osteonecrosis of the jaw associated with bisphosphonate use was published, stimulating numerous further reports and speculation on the etiology of this disorder. Most instances occurred in association with intravenous administration of bisphosphonates accompanying a chemotherapeutic regimen for multiple myeloma or breast or prostate cancer. The risk of osteonecrosis of the jaw related to *oral* bisphosphonate used for treatment of osteoporosis is estimated at 0.01% to 0.04%.²¹ The risk is higher for those with Paget disease and those being treated for malignancy, and the event is often triggered by dental work or trauma that leads to exposure of bone.²¹ In patients treated with zoledronic acid and/or pamidronate for myeloma, breast cancer, or prostate cancer the overall prevalence is about 5%.⁵ Proposed mechanisms include increased susceptibility of bone to infection and necrosis caused by decreased bone turnover²² and direct toxicity of high-potency bisphosphonates to bone cells.⁵

PATHOLOGIC FEATURES

Necrosis of all cellular components of bone, both in hematopoietic fat marrow and mineralized tissue, is the hallmark of osteonecrosis. Death of the cellular components of bone results in destruction of the osseous components of bone with structural consequences (Fig. 184.1).

In the early (prenecrotic) stage, there is interstitial edema and plasmolysis confined to the bone marrow, with occasional foam cells. The primary indication of necrosis of bone tissue is disappearance of osteocytes, the cavities of which are empty and often enlarged. As the severity progresses, the medullary spaces become filled with necrotic tissue, which is subsequently associated with trabecular necrosis and emptying of the lacunae. The bone sequestrum is composed of dead trabeculae without osteocytes but maintained architecture. The bone marrow tissue exhibits disappearance of stem cells, adipocyte nucleolysis, and membrane loss, often without persistence of recognizable cell remnants. Subchondral fracture, when present, is usually located in the dead bone, typically somewhat parallel to the edges of the epiphysis, which results in the characteristic radiologic “crescent sign.” Around the dead bone tissue is usually a zone of repair comprising fibrovascular proliferation, bone resorption, and new bone apposition on the remains of the old dead trabeculae.

At a macroscopic level, osteonecrosis is regional and highly circumscribed. It can be confined to a medullary section of bone or involve a periarticular segment such as the subcortical femoral head. The biomechanical consequences of osteonecrosis are largely contingent on its anatomic location and extent of involvement. Areas confined to a medullary location can be asymptomatic, whereas involvement of the subcortex adjacent to a joint surface leads to articular collapse and joint destruction. For individuals with polyarticular osteonecrosis, as can be seen in sickle cell disease, the condition can have devastating functional consequences.

Pathogenesis

In its simplest characterization, focal bone death results from a compromised arterial blood supply, a paradigm best exemplified by the posttraumatic form of osteonecrosis. However, in the spontaneous forms of osteonecrosis a pathologic basis for interruption of the blood supply is rarely clear. This conundrum has led to speculation about processes that could compromise the health of affected regions of bone and result from exposures known to be associated with osteonecrosis. Most of these involve a proposed vascular mechanism:

Fig. 184.1 Coronal section of a femoral head removed during total hip replacement. The cartilage above the sequestrum is of irregular height. Osteophytes of the superior and inferior aspects of the femoral head are present. There is a sclerotic border delineating the sequestrum. The trabecular architecture is otherwise preserved.

- Disturbances of fat metabolism
- Intravascular occlusion by coagulation, thrombi, fat emboli, abnormally shaped red blood cells
- Elevated intraosseous pressure
- Intramedullary hemorrhage
- Osteocytotoxicity

Other processes that might participate in the overall extent of destruction include the following:

- The reparative response itself
- Mechanical stress
- Inhibition of angiogenesis

Altered fat metabolism

Evidence indicates that increases in the amount of fat within the femoral head elevate intracortical pressure and lead to sinusoidal collapse.²³ Numerous studies have shown diverse effects of corticosteroid exposure on lipid metabolism and on differentiation of bone marrow–derived stem cells favoring adipocytogenesis.⁸ *In vivo* studies have confirmed that corticosteroids increase the fat content of the femoral head and that this increase correlates with an increase in intraosseous pressure and decreased blood supply.^{24–28} Interestingly, this effect has been abrogated by the administration of clofibrate, a lipid-lowering agent.²⁹ Steroids have also been shown to be capable of causing fat emboli in animal models.²⁴ Overall, these studies implicate an abnormality of fat metabolism and/or morphology that may compromise blood flow to the affected area through an increase in intraosseous pressure.

Although most of these studies originated in pursuit of a corticosteroid effect, it is pertinent that abnormalities of lipid metabolism have also been observed in patients with osteonecrosis attributed to alcohol use. Patients with alcohol-associated osteonecrosis frequently have elevated serum cholesterol and triglyceride levels,³⁰ and the cholesterol content of bone samples from patients with osteonecrosis has been found to be elevated.³¹ Abnormalities of trabecular fat cell size and bone marrow pressure have also been demonstrated in an alcoholic rabbit model.³² Alcohol also appears to induce differentiation of marrow stromal cells into adipocytes in a dose-dependent manner and reduces osteogenesis.³³

Intravascular coagulation

Intravascular coagulation of the intraosseous microcirculation, progressing to more generalized thrombosis, is a strong contender as a process leading

to osteonecrosis. Many of the conditions reported to be associated with osteonecrosis have attributes capable of triggering intravascular coagulation. This could occur as a primary event (as in antiphospholipid antibody syndrome¹⁵) or as a secondary reaction to some other process (such as thrombosis secondary to fat embolism).

Also, numerous gene abnormalities or polymorphisms associated with hypercoagulable states occur with increased frequency in individuals with osteonecrosis, including the mutations factor V Leiden and prothrombin 20210A, and deficiency of protein C or S. Several studies of coagulation factors have found abnormalities relating to plasminogen activator inhibitor in patients with osteonecrosis, which suggests reduced fibrinolysis as a potential risk factor.^{15,18-20} Such observations prompted a clinical trial of low-molecular-weight heparin, which slowed progression of osteonecrosis in patients with early-stage disease.³⁴

Elevated intraosseous pressure

As a nondistensible structure with a cortical shell, bone has limited capacity to accommodate an increase in space occupied within. Any such changes may elevate intracortical pressure and compromise blood flow.³⁵

Intramedullary hemorrhage

Intramedullary hemorrhage is frequently present in the vicinity of osteonecrotic lesions and is generally considered to be a secondary phenomenon. However, examination of osteonecrotic zones with recent hemorrhage has shown arteriopathy, which suggests that recurrent intramedullary hemorrhage may contribute to the pathogenesis of osteonecrosis.^{36,37}

Osteocytotoxicity

The histologic observations of absent or nonviable osteocytes in trabecular samples without osteonecrosis generate the possibility that osteocyte death may be a primary rather than secondary event in its development. Toxic accumulation of lipid droplets within the osteocytes apparently occurs with high-dose steroids and alcohol and can damage the cell membrane and lead to cell death.^{31,38} Recently it has also been determined that both alcohol and corticosteroids have adverse influences on bone cell lineage by enhancing adipogenesis and inhibiting osteocytogenesis by marrow stem cells.⁸

Other participatory processes

A number of other processes including attempts at repair may have sequelae that contribute to the progression of osteonecrosis. The presence of necrotic bone stimulates a number of cellular activities aimed at replacing necrotic bone with new bone. However, this process can be counterproductive in various situations, such as when the remodeling leads to a shift to compact bone or interrupts blood supply and attempts at revascularization.³⁹⁻⁴¹ Mechanical stress may also contribute to the progression of osteonecrosis. Two animal studies of osteonecrosis found a greater extent of osteonecrosis in the animals that were allowed to bear weight than in those that could not.^{42,43}

CLINICAL FEATURES

The clinical presentation of osteonecrosis is quite variable, with characteristics tending to reflect the anatomic region of localization. Osteonecrosis in the femoral head, for example, usually causes pain in the groin or anterior thigh. However, osteonecrosis can be asymptomatic, especially when confined to medullary bone. The pain from acute osteonecrosis can also be especially intense and may require opioid analgesics. It is differentiated from ordinary joint pain by its severity, presence at rest, lack of relationship to weight bearing, and (in early stages) preservation of joint range of motion. These clinical characteristics can be viewed as “red flags” for the possibility of osteonecrosis. With the development of articular collapse and secondary osteoarthritis, an osteoarthritic constellation of symptoms supervenes. Osteonecrosis is usually a unilateral phenomenon but can be bilateral and even multifocal.

Typical sites of involvement by osteonecrosis include the femoral head (the most common), the femoral condyles of the knee, the proximal tibia, the humeral head, the small bones of the foot and ankle, the wrist and hand bones, the vertebrae, and (less commonly) the facial bones.⁴

DIAGNOSIS

The clinical diagnosis of osteonecrosis is often substantially delayed. The primary reason for this is the insensitivity of radiography for its earliest features. Radiography may instead reveal minor osteoarthritic changes, to

which the pain is often misattributed. Indeed, the development of osteonecrosis in a joint with a prior diagnosis of osteoarthritis poses a particular clinical conundrum. Thus the presence of red flag clinical features should prompt a more sensitive imaging investigation, currently MRI.

A history of use of specific medications should raise the prior probability for this diagnosis in patients with known risk factors. These include exposures such as alcohol and corticosteroid use and diagnoses such as SLE or sickle cell or hemoglobin SC disease. Certain clinical scenarios should also increase vigilance for osteonecrosis, such as high-dose corticosteroid therapy in patients with SLE, acute hip pain in women in the third trimester of pregnancy, and a dramatic escalation of knee pain in individuals with knee osteoarthritis.

In general, the diagnosis of osteonecrosis is made through clinical evaluation and imaging. Blood tests may contribute information by establishing the presence of predisposing factors such as autoimmune disease, hemoglobinopathies, dyslipidemias, and systemic inflammatory disorders.

DIFFERENTIAL DIAGNOSIS

Among the subtypes of osteonecrosis are a small number that can be differentiated through their distinctive manifestations and that may represent separate disease entities. These include spontaneous osteonecrosis of the knee, subchondral fractures, osteonecrosis of pregnancy/transient osteoporosis of the hip, and transient regional osteoporosis. Other diagnoses that should be considered in the evaluation of severe joint pain include acute synovitis, soft tissue trauma (e.g., tear of the hip joint labrum), severe osteoarthritis, algodystrophy, and referred pain.

Bone infarct

Osteonecrosis is referred to as a *bone infarct* when it occurs within the diaphysis or metadiaphysis of the bone. The characteristics of bone infarcts differ somewhat from typical epiphyseal osteonecrosis but share many of the predisposing factors. The MRI appearance of focal bone infarcts contrasts with epiphyseal osteonecrosis because of differences between yellow and red marrow. Bone infarcts tend to reflect the characteristic bone marrow edema pattern seen in epiphyseal osteonecrosis (dark on T1-weighted and bright on T2-weighted sequences, with a geographic morphology). The T2-signal heterogeneity typical of epiphyseal osteonecrosis is not evident in bone infarcts. Radiographically, bone infarcts demonstrate a lytic appearance with serpiginous, well-defined geographic sclerotic borders.

Spontaneous osteonecrosis of the knee

Spontaneous osteonecrosis of the knee (SPONK), typically involving the medial or lateral tibial plateau and associated with severe knee pain, has been viewed as sharing the same pathologic basis as osteonecrosis of the femoral head (Fig. 184.2).⁴⁴ However, the syndrome may be somewhat heterogeneous in its manifestations⁴⁵ and may lack the typical features of epiphyseal osteonecrosis, which include a demarcation rim or reactive interface.⁴⁶ Recent scrutiny of histologic sections following knee arthroplasty performed for SPONK revealed that the pathologic process may originate as a form of subchondral stress fracture.⁴⁶ Subchondral fractures could result in infiltration of joint fluid into the trabecular space, causing a localized increase in medullary pressure and osteonecrosis. Some cases of SPONK have resolved without surgical intervention. Features on MRI that may indicate a benign course include the absence of focal epiphyseal contour depression or lines of low signal intensity deep in the condyle.⁴⁶

Osteonecrosis during pregnancy

Osteonecrosis of the hip occurring in pregnancy in women without any traditional risk factors for the disease is a rare but recognized phenomenon.⁴⁷⁻⁵⁰ No clear clinical patterns or associations are evident from the small number of cases described in the literature. The problem manifests as hip pain and is diagnosed using MRI or later becomes apparent on radiographs with clinical progression. Many cases have been treated with surgical intervention. Osteonecrosis during pregnancy can be confused with transient osteoporosis of the hip during pregnancy.⁴⁷

Idiopathic transient osteoporosis of the hip

Transient osteoporosis of the hip is a self-limiting skeletal disorder, usually affecting women in their third trimester of pregnancy, that resolves spontaneously within 12 months postpartum.⁵¹ It has been viewed as a variant of

Fig. 184.2 T1-weighted coronal magnetic resonance image of the knee (left) demonstrates subchondral linear dark signal with associated ill-defined low signal representing marrow edema. The proton-density fat-saturated coronal image (right) demonstrates marked marrow signal abnormality involving the medial femoral condyle with subchondral dark signal paralleling the articular surface. These findings indicate the presence of the now controversial entity known as *spontaneous osteonecrosis of the knee*.

Sudeck atrophy,⁵¹ but the exact cause remains unknown. It is characterized by disabling pain in the hip without prior trauma and by striking radiographic evidence of osteopenia that is limited to the hip. MRI shows bone marrow edema and occasionally joint effusion (Fig. 184.3). Bone mineral density is reduced, and this can be systemic.^{52,53} Clinical and radiographic findings regress spontaneously after pregnancy and generally without late sequelae. However, there are reports of cases complicated by pathologic fracture.⁵⁴ Transient osteoporosis of the hip has been described postpartum⁵⁵ and in a nonpregnant woman.⁵⁶ The condition has many clinical similarities to another rare disorder, *transient regional osteoporosis*, in which localized pain and osteopenia migrate from one skeletal site to another.⁵⁷ Treatment for idiopathic transient osteoporosis of the hip consists of joint protection with limited weight bearing, range-of-motion exercise, progressive ambulation, and analgesics. Antiresorptive agents have been used in some cases with reported benefit.⁵⁸

IMAGING

Historically, radiographs have been widely used for the diagnosis and evaluation of osteonecrosis. Definitive radiographic features of osteonecrosis (e.g., the crescent sign) are highly specific late in the disease but insensitive during the early phase (Fig. 184.4). Before the widespread availability of MRI, bone scintigraphy was advocated as a more sensitive test for early osteonecrosis. The technique offered advantages over plain radiography⁵⁹ and with optimal conditions may be more sensitive than conventional MRI, albeit less specific.⁶⁰ However, the technique is cumbersome, exposes people to ionizing radiation, provides low resolution, and discriminates poorly among osteonecrosis, fractures, transient osteoporosis, and other conditions. Current practice in the diagnosis of early-stage osteonecrosis requires an MRI scan. MRI scans have the greatest detection sensitivity for osteonecrosis and are less hazardous than radionuclide bone scans.

The American College of Radiology recommends anteroposterior and frog-leg radiography for initial evaluation of osteonecrosis of the hip.⁶¹ These two views provide an approximation of orthogonal views with which to evaluate the morphology and quality of the femoral head. If collapse is identified and immediate surgery is contemplated, the American College of Radiology recommends MRI to evaluate for occult osteonecrosis of the contralateral hip. In cases in which the morphology of the affected side is maintained but the head appears sclerotic or mottled, MRI should be performed to confirm the diagnosis of osteonecrosis. Negative radiographic

Fig. 184.3 Baseline magnetic resonance image showing increased signal in the left femoral head in a 30-year-old woman with idiopathic transient osteoporosis of the hip at 3 months postpartum.

findings in the setting of suspicion of femoral head osteonecrosis should always prompt an MRI examination. The American College of Radiology recommends the use of radionuclide bone scan as a second-line substitute in patients with contraindications to MRI.

Radiography

In the early stages of osteonecrosis plain radiographs typically show normal or negative findings. The earliest radiographic changes include diffuse osteopenia, serpiginous areas of radiolucency with a sclerotic border, and linear sclerosis typically adjacent to the joint margin. Later the subchondral radiolucency can organize into a crescent sign, and the appearance is pathognomonic for osteonecrosis (see Fig. 184.4). Later changes include flattening of the articular surface and sometimes gross collapse (see Fig. 184.4). Initially the joint space is normal, but structural collapse adjacent to articular cartilage typically leads to secondary osteoarthritis. In some cases this process results in total destruction of the involved structure such as the femoral head or humeral head.

Fig. 184.4 (a) Single view of the pelvis demonstrating vague increased density of the left femoral head raising suspicion of osteonecrosis. Magnetic resonance imaging was recommended for both hips to confirm the finding on the left and potentially identify early osteonecrosis in the contralateral femoral head before collapse. (b) Coronal short tau inversion recovery image (left) confirming avascular necrosis on the left characterized by a geographic lesion on the weight-bearing surface of the left femoral head. Coronal T1-weighted image (right) illustrating the typical pattern of bilateral geographic lesions low in signal. Of interest is the early osteonecrosis involving the radiographically normal right femoral head.

Radionuclide bone scan

Radionuclide bone scans were used to detect early osteonecrosis before the advance of clinical MRI. Bone scans obtained using methylene bisphosphonate labeled with technetium-99m were useful because they can exhibit increased uptake in the region of osteonecrosis before changes emerge on the radiograph. Bone scans may still have utility in situations in which MRI is contraindicated. However, the changes on bone scan are somewhat non-specific, it is not as sensitive as MRI, and it exposes the patient to radiation hazard.

Computed tomography

Computed tomography (CT) offer advantages over radiography due to multiplanar reformatting and improved contrast. CT is useful in defining the extent of cortical collapse in late disease as well as assessing the severity of secondary osteoarthritis. Such information is essential to determine surgical treatment options, which range from osteotomy to total hip arthroplasty. CT may be used in the setting of potential acute on chronic osteonecrosis to evaluate new-onset subtle articular collapse.

Magnetic resonance imaging

The characteristic appearance on MRI varies according to location. Within epiphyseal lesions, such as osteonecrosis of the hip, a typical area of normal marrow signal on T1 and T2 weighting is bordered by a dark line or rim (see Fig. 184.4). The line has been described as having a geographic appearance because it mimics the morphology of a coastline with its interstices. Over time, T2-bright signal parallels the inside margin of the lesion. This is often referred to as the characteristic *double-line sign*. The double-line sign is seen in approximately 75% of cases.⁶² The double-line sign likely represents chemical shift artifact related to the misregistration of adjacent fluid and fat voxels owing to their slightly differing precessional frequencies. As the lesion evolves, it is common to identify subchondral fracture just before collapse. The subchondral fracture line may appear bright on T2-weighted and dark on T1-weighted images. The signal characteristics of the lesion are highly variable. Over time, the lesion, if not revascularized, will appear dark on both T1- and T2-weighted images. Additionally, researchers have identified effusion in approximately 60% of cases.⁶³

MRI has its greatest utility in the early diagnosis of osteonecrosis in a variety of anatomic locations (Figs. 184.5 to 184.8) and also can detect a variety of disorders that can cause diagnostic confusion, such as subchondral insufficiency fracture (see Fig. 184.2) and bone infarcts (Fig. 184.9).

Staging systems

Several different staging classifications have been used to evaluate osteonecrosis. The most widely used system based on conventional radiographic findings is the Ficat staging system described by Ficat and Arlet (Table 184.1).⁶⁴ Over time, this classification system has been modified by other groups to assist in assignment of patients into one of two arms of therapy, intraosseous pressure reduction or joint reconstruction. Steinberg proposed a classification system that refines the Ficat system by including the findings

Fig. 184.5 Coronal proton-density magnetic resonance image of the shoulder illustrating collapse of the articular surface with a characteristic subchondral, low-signal, linear geographic pattern and adjacent marrow signal abnormality that was found to be osteonecrosis on pathologic analysis. (Courtesy Christopher G. Roth, MD.)

of bone scan and MRI as well as emphasizing volumetric assessment of femoral head involvement (Table 184.2). The Association Research Circulation Osseus, in its International Classification of Osteonecrosis of the Femoral Head, has also recently adopted an osteonecrosis staging system (Box 184.2).

MANAGEMENT

Although it is prudent to avoid risk factors such as glucocorticoid use and weight bearing on the affected limb, no conservative medical approaches are known to influence the outcome of osteonecrosis.⁴ Medical treatment options are also limited in scope. There is a long-standing view that load on the affected region should be reduced for 4 to 8 weeks. Crutches can be prescribed to accomplish this, but their effectiveness is unclear. Other

suggested interventions include physical therapy to maintain muscle strength and prevent contractures, and judicious use of analgesics.

Thus the critical management decisions for an individual with newly diagnosed osteonecrosis relate to whether to intervene surgically and which procedure to deploy. Conservative approaches have been tested in clinical trials and are advocated when the affected segment involves less than 15%

of the articular margin and is remote from the weight-bearing region.⁶⁵⁻⁶⁷ However, these conservative approaches do not generally prevent disease progression, which is the primary goal of any osteonecrosis intervention therapy. Overall, the clinical trials and retrospective observational studies comparing conservative treatment to surgical interventions of various types for hip joint osteonecrosis indicate that surgically treated joints generally have better outcomes.

■ **TABLE 184.1**

Ficat staging system

Stage I	Normal radiographic findings
Stage II	Sclerotic or cystic lesions
Stage III	Subchondral collapse
Stage IV	Osteoarthritis with articular collapse

Core decompression

The goals of core decompression are to reduce elevated intramedullary pressure, improve oxygenation of the ischemic region of the bone, and allow adjacent living bone to contribute to the reparative process. The procedure provides swift pain relief and appears to yield favorable results when performed at an early stage of osteonecrosis development. However, a meta-analysis of clinical trials of core decompression suggested that this intervention was superior to conservative treatment only when used to treat stage I

Fig. 184.6 Sagittal proton-density magnetic resonance image of the ankle demonstrating marked marrow signal change within the head of the talus. Differential considerations include fracture and osteonecrosis. The follow-up plain radiograph for this patient indicated avascular necrosis. (Courtesy Christopher G. Roth, MD.)

Fig. 184.7 Axial short tau inversion recovery (STIR) magnetic resonance image demonstrating bilateral avascular necrosis (AVN). Bilateral AVN is apparent on this coronal STIR image. A double-line sign is apparent on the right. Recent thinking attributes the sign to chemical shift artifact, a phenomenon that arises because of misregistration of adjacent fat and water due to slightly differing processing frequencies at a given field strength.

Fig. 184.8 Sagittal T1-weighted magnetic resonance image of the ankle (left) shows marked diffuse low signal of the navicular. The sagittal T2-weighted fat-saturated image (right) demonstrates corresponding diffuse high signal of the navicular, which suggests osteonecrosis. (Courtesy Christopher G. Roth, MD.)

Fig. 184.9 T1-weighted coronal magnetic resonance image of the knee illustrating a geographic lesion in the tibial metaphysis consistent with a bone infarct. (Courtesy Christopher G. Roth, MD.)

TABLE 184.2
Steinberg staging system

Stage I	Normal radiographic findings; abnormal bone scan and/or magnetic resonance imaging findings Mild (<15% of head affected) Moderate (15%-30% of head affected) Severe (>30% of head affected)
Stage II	Lucent and sclerotic changes in the femoral head Mild (<15% of head affected) Moderate (15%-30% of head affected) Severe (>30% of head affected)
Stage III	Subchondral collapse without flattening Mild (<15% of head affected) Moderate (15%-30% of head affected) Severe (>30% of head affected)
Stage IV	Flattening of the femoral head Mild (<15% of head affected) Moderate (15%-30% of head affected) Severe (>30% of head affected)
Stage V	Joint narrowing and/or acetabular changes Mild Moderate Severe
Stage VI	Advanced degenerative changes

BOX 184.2 INTERNATIONAL CLASSIFICATION OF OSTEONECROSIS OF THE FEMORAL HEAD (ASSOCIATION RESEARCH CIRCULATION OSSEUS)

Stage 0: Bone biopsy results consistent with osteonecrosis; other test results normal

Stage I: Positive findings on bone scan, magnetic resonance imaging (MRI), or both

A: <15% involvement of the femoral head (MRI)

B: 15% to 30% involvement

C: >30% involvement

Stage II: Mottled appearance of femoral head, osteosclerosis, cyst formation, and osteopenia on radiographs; no signs of collapse of femoral head on radiographic or computed tomographic study; positive findings on bone scan and MRI; no changes in acetabulum

A: <15% involvement of the femoral head (MRI)

B: 15% to 30% involvement

C: >30% involvement

Stage III: Presence of crescent sign lesions classified on basis of appearance on anteroposterior and lateral radiographs

A: <15% crescent sign or <2-mm depression of femoral head

B: 15% to 30% crescent sign or 2- to 4-mm depression

C: >30% crescent sign or >4-mm depression

Stage IV: Articular surface flattened; joint space shows narrowing; changes in acetabulum with evidence of osteosclerosis, cyst formation, and marginal osteophytes

lesions.⁶⁸ The procedure also carries risks, which include hip fracture, post-operative infection, and suboptimal results.

Other orthopedic interventions for osteonecrosis

A variety of bone graft procedures, often in combination with other operative techniques, can be performed with the intent of delaying the need for arthroplasty. Various types of osteotomies are also performed to shift the necrotic bone segments away from the weight-bearing zone. Long-term outcome data for these procedures are scarce.

Arthroplasty

The development of substantial joint damage and secondary osteoarthritis leaves arthroplasty as the treatment of choice. The stage and extent of disease, as well as the age of the patient, all determine the type of arthroplasty procedure. Unfortunately, patients with osteonecrosis have poorer outcomes following total hip arthroplasty than individuals with osteoarthritis.⁶⁹

Experimental therapies

Various attempts have been made to enhance the healing of osseous defects in the femoral head before collapse occurs. In a recent clinical trial, low-molecular-weight heparin appeared to slow progression of osteonecrosis in patients with early-stage disease.³⁴ Other candidate noninvasive treatment modalities include pharmacologic measures, electrical stimulation, shock wave therapy, and electromagnetic field therapy.⁶⁷ Clofibrate is capable of abrogating the increase in fat content in the femoral head that precedes the development of osteonecrosis in a rabbit model.²⁹ The cholesterol-lowering agent lovastatin has also shown promise *in vitro* and *in vivo* for preventing the development of steroid-induced osteonecrosis.^{28,70} Puerarin, a compound with antioxidative and antithrombotic effects, has been proposed as a preventative for alcohol-induced adipogenesis and osteonecrosis.⁷¹ Future directions may involve growth and differentiation factors, cytokines, angiogenic factors, and bone morphogenetic proteins.

Rare osteoarthritis: ochronosis and Kashin-Beck disease

■ VIRGINIA BYERS KRAUS

OCHRONOSIS

- Ochronosis is a rare autosomal recessive disorder resulting from a constitutional lack of homogentisic acid oxidase.
- In ochronosis, homogentisic acid undergoes autooxidation as well as enzymatic oxidation and polymerization to form an ochronotic pigment that accumulates in cartilage and connective tissues.
- The endogenous form of ochronosis may be confused with exogenous ochronosis, a limited hyperpigmentation of skin caused by various drugs and chemicals.
- Clinical features of ochronosis include homogentisic aciduria, pigmentation of cartilages and other connective tissues, and, in later years, generalized osteoarthritis of the spine and large joints, termed *ochronotic arthropathies*.

KASHIN-BECK DISEASE

- Kashin-Beck disease is a severe, progressive osteoarthropathy of unknown cause endemic to China and Tibet, with onset in childhood.
- Three interacting causal mechanisms have been proposed, including a deficiency in trace elements (selenium and iodine), exposure to organic matter in contaminated drinking water, and contamination of food by noxious mycotoxins.
- The disease is characterized by necrosis and remodeling of cartilage including growth plates.
- Clinical features of Kashin-Beck disease include generalized osteoarthropathy involving the ankles, knees, interphalangeal joints, wrists, and elbows with foreshortened phalanges; more severe involvement of distal and lower limbs; and an association with short stature.

INTRODUCTION

Osteoarthritis (OA) comprises a heterogeneous group of joint diseases, some of common and some of rare occurrence. Although the rare forms discussed here impact individuals infrequently or in specific and circumscribed geographic regions, nevertheless an understanding of these rare forms of OA may provide useful insights into the nature and pathogenesis of the more common varieties of OA. These rare forms of OA are thought to derive from diverse causes that include genetic determinants (ochronosis), and a combination of genetic, nutritional, and biogeochemical factors (Kashin-Beck disease). This diversity of causes is itself illustrative of the multiple pathways to the syndrome of joint failure that we recognize as OA. Although each of these diseases presents clinically as a form of OA, there are differentiating manifestations by which these arthropathies can be distinguished from one another. An appreciation of these subtleties is key to the recognition and management of these disorders.

OCHRONOSIS

History

Ochronosis and *alkaptonuria* are two names that refer to different manifestations of the same condition resulting from an inborn error of tyrosine

metabolism—a deficiency of the enzyme homogentisate 1,2-dioxygenase (HGO) (Fig. 185.1). The connection between these two entities was recognized by Albrecht in 1902.¹ Simultaneously, this was the first human disorder found to conform to the principles of mendelian autosomal recessive inheritance.² In 1908 the term *inborn errors of metabolism* was first coined by Archibald Garrod to describe this and three other diseases.³ The absence of the HGO enzyme, normally highly expressed in hepatocytes,⁴ leads to the accumulation of metabolites of homogentisic acid in the connective tissues of individuals who are affected; this deposition causes an ochrelike pigmentation in the skin, sclera, and cartilages of the body (Fig. 185.2) and is the characteristic for which the disease was named *ochronosis* by Virchow. Only a small proportion of the homogentisic acid formed endogenously is normally retained in the body because of its high renal clearance⁵; the absence of the HGO enzyme leads to abundant urinary excretion of homogentisic acid, which darkens slowly upon oxidation by prolonged exposure to air. The darkening is hastened by the addition of alkali to the urine and is reflected in the original term for homogentisic acid, *alkapton*, which refers to its avidity for alkali. The distinctiveness of alkaptonuria accounts for reports of dark urine, including urine “as black as ink,” dating as far back as the Middle Ages.¹ There has even been biochemical confirmation that ochronotic pigment in the bone and articular hip cartilage of an Egyptian mummy originated from homogentisic acid, which demonstrates that this disorder has afflicted humans since ancient times.⁶

Epidemiology

Alkaptonuria/ochronosis is one of the rare diseases that affect human beings on a worldwide scale.⁷ In the United States, alkaptonuria has a prevalence of 1 case per 250,000 to 1 million live births.⁸ This disorder occurs worldwide, with the highest frequencies reported in Slovakia and the Dominican Republic, in which the prevalence approaches 1 case per 19,000 inhabitants,⁹ and in a single village in southern Jordan with large number of cases (40 individuals in 17 families) considered a probable consequence of the high rates of consanguineous marriages in Jordan.¹⁰

Clinical features

The patient with ochronosis is distinguished by the triad of dark urine on addition of alkali, ochronotic pigmentation, and arthritis.¹¹ Alkaptonuria is present at birth and is often diagnosed by discoloration of the diapers. This is the only sign of the disorder in the pediatric age group,¹² and many patients remain undiagnosed until adulthood because 25% do not have the characteristic dark urine staining.¹³ It is possible that many of the early manifestations of this disorder may go unnoticed by the patient, including dark urine and dark cerumen at birth, axillary pigmentation at puberty, and earlobe skin and scleral pigmentation at 20 to 40 years of age.¹⁴ Cases that escape detection in childhood are usually diagnosed on the basis of chronic joint pain, which typically develops in the third decade of life.² The delay in appearance of the ochronotic arthropathy until after midlife is often ascribed to a waning efficiency of the renal clearance of homogentisic acid leading to an accelerated accumulation of homogentisic acid oxidation byproducts with aging.¹⁵

The arthropathy that develops affects the spine and large joints. The low back is frequently the signal anatomic site. The spine involvement resembles ankylosing spondylitis but differs in sparing the sacroiliac joints.² The pattern of spine involvement is reported to differ from typical OA in that thoracolumbar changes predominate rather than lumbosacral degeneration,¹⁵ although the severity of lumbar spine involvement had the strongest correlation with disability measures in a study of 53 patients.¹⁶ Narrowing and dense, waferlike calcification of the intervertebral disks are the most

Fig. 185.1 Ochronosis. Pathways leading to pathologic manifestations of ochronosis (alkaptonuria). (Adapted from references 2, 8, and 19.)

Fig. 185.2 Ochronosis. Black-gray pigmentation of the ear cartilage in a patient with ochronosis.

characteristic findings in the spine (Fig. 185.3), and osteophytes are said to be usually absent or of small size.^{17,18} The peripheral arthritis closely resembles that of OA; however, hands and feet are usually spared.¹⁹ Arthritis of the peripheral joints is generally observed about 10 years after spinal changes (Fig. 185.4). The main differences between ochronotic arthropathy, primary OA, and ankylosing spondylitis are summarized in Table 185.1. Tendon involvement is typically symmetric and involves traction tendons and their insertion sites with characteristic changes of enthesopathy, in general sparing tendons with synovial sheaths.²⁰ Tendon and ligament ruptures are reported to occur with minimal provocation.^{2,21} Pain, stiffness, crepitation, flexion contractures, and limitation of motion are the most common clinical features.¹⁸ Loose (osteochondral) bodies may cause joint-locking episodes.¹⁸

Increased bone resorption and osteoporosis have also been documented in association with ochronosis, even in the absence of immobility.²² Other disease manifestations include renal and prostate stones, aortic valve calcification and stenosis, and coronary artery calcification.⁸ Because intense pigment deposition is found in the aortic root and minimal pigmentation is seen in the venous circulation, a role has been posited for blood pressure and hemodynamic factors in explaining the differential tissue susceptibility to ochronotic pigmentation and pathologic changes.²³

Investigations

Noninvasive

The diagnosis of alkaptonuria/ochronosis is suspected when there is bluish black pigmentation of the sclerae and the cartilages of the ears and nose, and darkening of the urine on standing in air or with the addition of alkali (10 drops of 10% NaOH to 20 mL urine per Zhao²⁴). The diagnosis is

■ **TABLE 185.1**
Characteristics of ochronotic arthropathy versus primary osteoarthritis and ankylosing spondylitis

	Ochronosis	Osteoarthritis (primary)	Ankylosing spondylitis
Joints involved	Spine+++ Knees+++ Hips++ Shoulders+	Spine+++ Knees++ Hips++ Hands+++	Spine+++ Knees+ Hips+
Distinguishing spine features			
Sacroiliac joints	Spared	Spared	Involved

Multiple vacuum disks	Common	Rare	Rare
Syndesmophytes	Broad	None	Thin + vertical
Apophyseal facet joint disease	Mild	Mild-severe	Severe
Ligamentous ossification	Prominent	Scarce	Scarce

Adopted from Konttinen YT, Hoikko V, Lomdmon M, et al. Ochronosis: a report of a case and a review of literature. Clin Exp Rheumatol 1989;7:435-44.

Fig. 185.3 Ochronosis. Radiographs of the spine showing narrowing and calcification of the intervertebral disks.

confirmed by 24-hour urinary excretion of homogentisic acid, measured by gas chromatography or high-performance liquid chromatography, that is higher than 0.030 to 0.040 mmol/mmol creatinine for children aged 1 to 6 years and 0.017 mmol/mmol creatinine for individuals from age 7 years through adulthood.²⁵ In addition, significant laboratory artifacts in alkaptonuria include the following: a false-positive urine Clinitest result for sugars caused by the reduction of copper by homogentisic acid¹⁸ and a falsely low urinary creatinine level if measured by an enzymatic method due to interference by homogentisic acid.²⁶

The extent of arthropathy is typically documented radiographically, and profound osteoarthritic changes in the large joints and the spine with extensive calcification of intervertebral disks characteristically are seen. Magnetic resonance imaging can readily detect ligamentous lesions.²⁷ Bone turnover and bone mass can be determined by quantification of N-telopeptides of type I collagen in the urine and by dual-energy x-ray absorptiometry (DXA) of the femur but not by DXA of the spine, for which bone mineral density measurements are spuriously overestimated due to intervertebral disk calcification and osteophyte formation.²²

Invasive

Macroscopic inspection of the joint during surgery shows darkened cartilage. Biopsy of affected tissues reveals the characteristic yellow-brown pigment in unstained sections, both free and intracellularly; the pigment typically is seen in macrophages, but researchers have also found pigment in chondrocytes, osteocytes, osteoblasts, osteoclasts, and fibroblasts.^{28,29} In cartilage the ochronotic pigmentation is most severe in the deep layer of cartilage, known to be a region of low protein turnover, whereas the articular surface, the region with the highest level of protein turnover, shows little pigmentation (Fig. 185.5a).³⁰ Ochronotic fragments of cartilage are found embedded in synovium where they evoke foreign body reactions with multinucleated giant cells.³¹ Ochronotic fragments of cartilage are also found in the joint cavity where they form a nidus for the development of osteochondral bodies.¹¹ Although the molecular basis for this is unclear, by electron microscopy ochronotic pigment has been observed deposited on collagen fibrils of joint capsule and cartilage, often in a distinctive pattern with some association with the periodicity of collagen cross banding (Fig. 185.5b).^{29,32}

as well as pigment invasion and disordering of collagen structure.³³ This distinct pattern of ochronotic pigment deposition can be reproduced by 5 to 7 days of *in vitro* culture of osteosarcoma cell lines and chondrocytes in a culture medium supplemented with homogentisic acid.^{28,34} Interestingly, bone collagen is largely unaffected, which indicates that mineralization of the collagen fibers *in vivo* prevents deposition of ochronotic pigment.³⁵ Homogentisic acid, the toxic agent in alkaptonuria, was recently identified as a member of a new chemical group of fibroblast growth inhibitors,³⁶ which suggests that the pigment itself may have some antianabolic characteristics that would inhibit the ability of joint tissue to respond to the pathologic insult induced by the deposition of pigment. This may, at least in part, explain the general lack of osteophyte formation as described earlier. It has recently been demonstrated that ochronotic pigment colocalizes with amyloid in osteoarticular tissues and is associated with high plasma levels

of serum amyloid A and P proteins,³⁷ which suggests that secondary amyloidosis occurs in response to the inflammation invoked by ochronotic pigment. Synovial effusions are reported in about half of cases, with cell counts of 100 to 700 cells/mm³ and a predominance of mononuclear cells.^{15,18} In one report, an aspirate from an affected joint yielded a synovial fluid with a speckled “ground pepper” appearance and dark cytoplasmic inclusions in mononuclear and polymorphonuclear cells.¹¹ Unlike urine, synovial fluids reportedly have low concentrations of homogentisic acid and fail to darken upon addition of alkali.¹¹ Homogentisic acid and its oxidation byproduct, benzoquinone acetic acid, react positively with Nile blue sulfate variant I stain, originally developed for identification of melanin,³⁸ and also turn black when stained with methylene blue or cresyl violet.¹⁸

Differential diagnosis

Alkaptonuria may be confused with several other conditions that cause dark urine, including porphyrias, the ingestion of indole compounds, myoglobinuria, hemoglobinuria, hematuria, bilirubinuria, and the presence of urobilinogen when oxidized to urobilin.¹⁸ The endogenous form of ochronosis may also be confused with exogenous ochronosis. Exogenous ochronosis refers to ochrelike pigment deposition in the skin, and sometimes in cartilages or other organs, as a result of exposure to a variety of exogenous compounds. Compounds implicated as causative agents of exogenous ochronosis include topical phenol formerly used as an antiseptic, topical hydroquinone bleaching creams, quinine injections, oral antimalarial drugs, amiodarone, cytotoxic drugs, minocycline,³⁹ and levodopa and methyldopa used in the treatment of Parkinson disease.⁴⁰ In most cases, long-term exposure to the inciting agent is necessary for the development of hyperpigmentation. Reversal is slow or nonexistent. These cases are distinguished from endogenous ochronosis by lack of urinary homogentisic acid excretion, genetics, and, in some cases, biopsy findings. No clear clinical effects beyond the cosmetic ones have been delineated for exogenous ochronosis. Thus it is necessary to appropriately distinguish exogenous from endogenous ochronosis, both to determine prognosis, which is more favorable for exogenous ochronosis, and to recommend the appropriate therapy, as described later, for an individual with endogenous ochronosis.

Pathogenesis

The tissue accumulation of homogentisic acid and its oxidation byproduct, benzoquinone acetic acid, is thought to be responsible for the clinical manifestations and severe arthropathy of ochronosis.⁴¹ Homogentisic acid can

Fig. 185.4 Ochronotic arthritis of the shoulder. Radiograph demonstrating characteristic osteoarthritis pathologic features including narrowing of the joint space, marked subchondral sclerosis, and small osteophytes.

Fig. 185.5 Ochronosis. (a) Photomicrograph showing the presence of ochronotic pigment in the cartilage from a femoral condyle of a patient with alkaptonuria. Pigmentation appears as a gradient and is most severe in the deep layers of cartilage; the articular surface shows little pigmentation (hematoxylin-eosin, $\times 4$). Inset: Chondrocytes located on the border between dense and light extracellular pigment. Chondrocytes show intracellular pigmentation and in some instances signs of necrosis (hematoxylin-eosin, $\times 10$). The evidence suggests that pigmentation occurs initially at the deep layers of cartilage before progressing toward the articular surface. (b) Transmission electron micrograph showing collagen fibers of ligamentous capsule from a patient with alkaptonuria. Collagen fibers have numerous electron-dense deposits of ochronotic pigment located along the fiber body. Deposits show some association with collagen cross banding. Not all fibers have deposits (stained using 1% aqueous osmium tetroxide solution and 5% alcoholic uranyl acetate, post-stained using lead citrate and uranyl acetate, $\times 60,000$). (Courtesy Dr. Adam M. Taylor, findAKUre project, University of Liverpool.)

undergo both autooxidation and enzymatic oxidation and polymerization to form an ochronotic pigment in the presence of the enzyme homogentisic acid polyphenol oxidase, present in skin and cartilage⁴¹ (see Fig. 185.1). High levels of homogentisic acid perturb collagen assembly and structure *in vivo* and *in vitro*.^{32,33} The infiltrated cartilaginous tissues become stiff³⁰ and brittle, and fissure and fragment readily. In addition, benzoquinone acetic acid may inhibit lysyl hydroxylase,¹ thereby reducing cross-linking of types I and II collagen and further impairing the ability of menisci and articular cartilage to resist stress and shearing injury. Finally, homogentisic acid also inhibits cell growth *in vitro* in a dose-dependent manner.¹ The concentrations of homogentisic acid (1 to 5 µg/mL) that proved to be cytotoxic in one *in vitro* study⁴² corresponded to plasma concentrations reported for patients with alkaptonuria (3.0 to 27.8 µg/mL).² Injected in high concentrations into joints of rabbits, homogentisic acid caused swelling, limitation of motion, and articular cartilage necrosis.⁴³

Genetics

In 1901 Garrod suggested an inherited cause of alkaptonuria⁵ based on observation of a family with two affected siblings and consanguinity of the parents. In 2007, clinical images of the eye, ear, and spine were published showing the progression to ochronosis by age 60 of the infant with alkaptonuria originally identified by Garrod.⁹ It is now well established that the accumulation of homogentisic acid and its oxidation products occurs through a deficiency of the HGO enzyme. The HGO enzyme is a hexamer consisting of two trimeric subunits.¹ The proper folding or association of the HGO subunits can be readily abolished by nonsynonymous (affecting a change in an amino acid) point mutations in the HGO gene on chromosome arm 3q, which eliminates the function of the HGO enzyme at the sites of its tissue expression: liver, kidney, small intestine, colon, and prostate⁴⁴—and, as recently described, chondrocytes, synoviocytes, and osteoblasts.⁴⁵ To date, a total of 119 different HGO mutations have been reported.^{46,47} With the exception of several mutations affecting individuals from the high-prevalence areas of Slovakia and the Dominican Republic, most of these HGO mutations are unique and specific to particular families with the disorder. The occurrence of a few specific mutations in the high-prevalence areas is taken as evidence for mutational hot spots within the HGO gene or founder effects^{2,9}—the consequence of a population arising from a small number of genetically isolated individuals, one or more of whom had the gene mutation. To date, no apparent correlation has been discerned between a patient's genotype and the level of excreted homogentisic acid,⁴⁸ nor have there been clear correlations between specific genotypes and clinical manifestations, including age of onset of symptoms²; a functional enzyme assay is thought to be required to accurately predict the pathogenicity of specific HGO variants.⁴⁸

Animal models

The mouse gene homologue of human alkaptonuria was mapped in 1994 through creation of a mutant mouse strain.⁴⁹ In another animal model, an arthropathy resembling ochronosis was induced in rats by feeding a diet with 8% L-tyrosine for 9 or more months starting at 1 month of age.³⁸ In a third animal model, injection of homogentisic acid into the joints of rabbits produced joint lesions that were similar to those of ochronosis, including the deposition of pigment within the synovium, synovial thickening, and granulomatous reaction in response to embedded fragments of damaged cartilage or tendon. This pathologic process could be ascribed directly to homogentisic acid rather than acidity because similar results were observed with both unbuffered and buffered (pH 7) homogentisic acid solutions.⁴³ Finally, a recent report documented the first histologic evidence for ochronosis of tissues in a murine transgenic model of alkaptonuria⁵⁰; of note, macroscopic and microscopic evidence of ochronosis was first observed at 13 months of age and was most readily identified by Schmorl staining. These animal models, the latter in particular, may be of use for studies of the pathogenesis of this disorder and provide model systems in which to evaluate potential therapies.

Management

The current approach to the treatment of musculoskeletal manifestations of alkaptonuria consists of standard therapy for OA with judicious use of joint replacement when warranted. In one prospective study of the natural history of the ochronotic disease process, the average age of joint replacement in patients was lower (53 years) than the national mean (67 years).¹⁶ This study also noted that a history of regular swimming correlated with less kyphosis and scoliosis and a trend toward higher vitality, physical role, and

mental health scores on the SF-36 Health Survey. Based on this study, treatments likely to benefit the physical function of these individuals include regular swimming, spine mobilization, and development of good truncal strength initiated early in the disease process.¹⁶ There has been one report of the disappearance of alkaptonuria and the cessation of ochronotic lesions following liver transplantation for hepatitis B-related cirrhosis.⁴ Surveillance for aortic dilatation and valvular calcification is recommended, as well as intervention for prostate and renal stones as needed.⁵¹

Although no specific pharmacologic therapy yet exists, the compound nitisinone (Orfadin), which has the chemical name 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione and was approved by the U.S. Food and Drug Administration in 2002 for the treatment of hereditary tyrosinemia, has been investigated for use in ochronosis.^{2,52,53} This drug inhibits the enzyme 4-hydroxyphenylpyruvic acid dioxygenase that produces homogentisic acid (see Fig. 185.1). A prospective randomized clinical trial involving 40 patients who were treated for 3 years with 2 mg nitisinone orally once daily showed a reduction of 95% or more in urine and plasma homogentisic acid levels and few adverse effects (one case each of corneal keratopathy and hepatotoxicity); however, hip range of motion and musculoskeletal function were not significantly different between treated and nontreated groups, although the trend in all these outcome measures favored the nitisinone group at study completion.⁵³ Of patients lacking aortic stenosis at baseline, none of the 18 nitisinone-treated patients compared with 7 of 17 control patients developed aortic sclerosis or stenosis by study completion.⁵³ Of note, patients could not be masked as to their treatment group because their urine color revealed the impact of nitisinone. These results suggest that this therapy is worth further study, but a longer trial, different primary endpoints, and/or a younger patient group may be required to demonstrate clinical efficacy. The estimated half-life of nitisinone of 54 hours may ultimately permit even less frequent dosing than once daily. Standardized clinical assessment tools for alkaptonuria have been developed^{54,55}; these are expected to facilitate longitudinal clinical assessments of patients.

Other treatments have included dietary restriction of protein to limit tyrosine and phenylalanine intake, although this was not required in the clinical trial described earlier. Compliance with these restrictions is reported to be difficult for adults, and long-term clinical trials of dietary therapy for alkaptonuria/ochronosis have not been conducted. Low-dose methotrexate was recently suggested to potentially inhibit the secondary production of amyloid in patients with alkaptonuria.³⁷ Antioxidants have also been proposed for the treatment of alkaptonuria based on the ability to counteract both the polymerization and accumulation of homogentisic acid, and the deleterious effects of free radicals generated in the course of homogentisic acid oxidation.¹ Antioxidants studied to some extent to date include ascorbic acid (vitamin C), N-acetylcysteine, phytic acid, and vitamin E as well as taurine, ferulic acid, and lipoic acid.^{56,57}

For many years ascorbic acid was considered a potential therapy for ochronosis based on a mechanism of action of inhibition of homogentisic acid polyphenol oxidase⁵⁸ responsible for producing the oxidized and polymerized byproducts of homogentisic acid (see Fig. 185.1). Consistent with this proposed mechanism of action, ascorbic acid inhibited the binding of a radiolabel derived from a homogentisic acid precursor to connective tissues in a rat model of alkaptonuria⁵⁹ and decreased the excretion of benzoquinone acetic acid in the urine.⁶⁰ In one report, transient (about 12-day) enhancement of homogentisic acid urinary excretion was achieved by ascorbic acid (500 mg twice daily) in 2 of 3 patients.¹⁹ On a cautionary note, ascorbic acid may serve as a cofactor for 4-hydroxyphenylpyruvic acid dioxygenase (see Fig. 185.1) and therefore may increase the production of homogentisic acid in alkaptonuria through this mechanism.⁶¹ Clinical outcomes of long-term treatment with ascorbic acid (0.25 to 4 g/day) have varied, and overall it has not been dramatically effective; however, controlled trials have never been conducted.

KASHIN-BECK DISEASE

History

Kashin-Beck disease (KBD) was first reported in Siberia in 1849 by a Russian surveyor, M. Jurenskij, who noted that some residents of the Urov River Valley of Russia had shortened fingers, showed a characteristic gait, and could neither walk nor work properly.⁶² In 1859 the physician Nikolai Kashin, assigned to a Cossack brigade, was ordered to investigate the disease causing deformities that prevented a segment of the local population from serving in the army.⁶² He concluded that “goiter, rheumatic pain, and cretinism” was an endemic disease, and it came to be known as *Urov disease*.

Evgeny Beck later added a systematic epidemiologic survey of this disorder in 1906, noting a prevalence of 6% to 46% (mean, 32%). KBD was first reported in China in 1908.⁶³ The world's literature on KBD was summarized in 1994 by Allander.⁶⁴ Skeletal remains indicate that it goes back to at least the 16th century.⁶⁴

Epidemiology

KBD is endemic in a region extending diagonally from northeastern China to Tibet in the southwest, with additional endemic regions in neighboring areas of Russia and some regions of Vietnam and Korea.⁶⁵ According to the 2008 health statistics issued by the Chinese Ministry of Health, there are currently 714,822 individuals affected by KBD in 2253 villages; this represents a KBD prevalence of 0.2% in the endemic villages (www.moh.gov.cn/publicfiles/business/htmlfiles/zwgkzt/ptjty/200805/35671.htm). In nongovernmental reports, the prevalence of KBD is described to be 8% to 43% in heavily affected areas.⁶⁶ KBD is mainly a disease of poor farming families,⁶⁷ on whom it imposes a severe socioeconomic stress.⁶⁸ These endemic regions are known for especially low environmental levels of the essential trace element selenium⁶⁹ and, consequently, low selenium levels in the blood and tissues of the native peoples consuming food from these areas.⁷⁰ The population mean serum selenium concentration in this region is less than 0.020 mg/L,⁷¹ whereas serum selenium concentrations in healthy persons have been found to average 0.066 to 0.104 mg/L.⁷² In China, the geographic distribution of KBD corresponds most closely to the areas of lowest selenium in water, soil, and food grains,^{69,73} and fluctuations in disease status are reported to correspond to fluctuations in serum selenium concentration,⁶⁹ the so-called wave character in morbidity.⁶² The daily intake of selenium in the Shaanxi KBD endemic area of China was quantified as 4.6 µg/day compared with 10.5 µg/day for nonendemic areas.⁷⁴ Both levels are well below the U.S. recommended daily allowance (RDA) of 70 µg for men and 55 µg for women. Within low-selenium areas, the reliance on river water for drinking has been associated with increased risk of disease in KBD areas, although selenium levels of the various water sources under study were not cited.⁷⁵ Eating corn, wheat, and barley has also been associated with KBD, whereas eating rice appears to be protective^{67,69}; interestingly, rice grown in KBD-endemic areas has a higher selenium content and selenium bioavailability than corn or wheat, which possibly accounts for its apparent protective effect.

Although a geographic association between KBD and selenium deficiency has been reported, KBD does not occur in every selenium-deficient area of China.⁷¹ Therefore, to gain a comprehensive understanding of risk factors for KBD, a cross-sectional epidemiologic study was conducted in 12 rural villages in Tibet in which 575 children aged 5 to 15 years were examined. The variables independently associated with KBD were found to be higher age, male gender, low socioeconomic status, a poorly diversified diet, iodine deficiency, and the use of smaller water containers.⁶⁷ Individuals were also at greatest risk of KBD if they had a sibling with the disease. In this study, selenium deficiency was severe in both KBD-affected and unaffected children, whereas low urinary iodine, high serum thyrotropin, and low serum thyroxine-binding globulin values were associated with an increased risk of KBD. Goiter secondary to iodine deficiency was found more often in villages affected by KBD than in control villages.⁷⁶ In general, selenium deficiency is closely associated with iodine deficiency in KBD areas.^{71,76} In one KBD-endemic area of China, urinary iodine levels were found to be 40% lower in KBD-affected children than in unaffected children.⁷⁷ Although iodine deficiency doubled the odds of KBD in this Chinese cohort, selenium deficiency was associated with a 61-fold increase in the odds of KBD.

In China, foodstuffs such as corn have commonly been stored in cave dwellings, where it is thought mycotoxins enter the food chain. In Tibet, too, a striking association was found between KBD and moldy grain from storage in a tent out of doors, which further suggests a pathogenic role for mycotoxins.⁶⁷ Fungal contamination of barley grain was related to the highest percentage of KBD cases (65%). Three fungal taxa isolated from barley samples were independently associated with KBD (*Trichothecium roseum*, *Alternaria* species, and *Dreschlera* species). The KBD prevalence rate increased dramatically from 13% if none of these taxa was isolated to 51% if one taxon was found and 89% if two or more taxa were isolated. This study provided strong support for a multifactorial cause of KBD in Tibet. Since then, numerous *in vitro* and animal studies have documented the deleterious effect of mycotoxins on cartilage.⁷⁸⁻⁸³

Evidence for hyposelenosis in non-KBD areas suggests that other risk factors, in addition to selenium deficiency, contribute to the pathogenesis of KBD. For instance, hyposelenosis exists in non-KBD areas such as Scandinavia, New Zealand,⁸⁴ Poland,⁸⁵ Central Africa, and the Democratic

Republic of the Congo,^{71,86} although the degree of deficiency in these areas may not be as profound as in the KBD-endemic areas.⁸⁶ Nevertheless, recent data suggest that milder degrees of selenium deficiency are associated with deleterious musculoskeletal consequences. In a population-based study in Johnston County, North Carolina, low selenium levels have been associated with increased odds of knee and hip OA.⁸⁷ In this regard, it is interesting to note an observation attributed to Kravencho in 1959 that an inordinate degree of OA developed in individuals who moved into endemic areas of KBD after the age of 25.⁸⁸ In addition, selenium levels were found to be significantly lower in men than in women in this American cohort.⁸⁷ As for many essential nutrients, the RDA for selenium is higher for men than for women to compensate for their larger body mass. Thus it is possible that selenium levels in men may more readily fall below a critical level necessary for joint tissue health under conditions of severely limited intake. The possibility that insufficient selenium intake may impact males more readily suggests a possible rationale for the consistent reports of a higher prevalence of KBD in males.

Clinical features

KBD usually becomes evident in children between 5 and 15 years of age.⁷⁶ Joint pain is the earliest symptom. For purposes of epidemiologic studies, a diagnosis of KBD has required symptom onset before the age of 30 years to clearly differentiate it from primary OA.⁸⁹ An increasing number of joints are involved from childhood to the age of 25 years in a slowly progressive osteoarthropathy.⁹⁰ The particular manifestations of the disease are symmetric and may vary with the time in life of exposure to the endemic environment. The arthropathy progresses to severe joint dysfunction, enlargement, and deformity. The Chinese characters for this disease, when literally translated, mean "big joint disease"⁶⁴ (Fig. 185.6). The most distal joints of the upper and lower limbs (lower more than upper) are most often and most severely affected,^{91,92} including the ankles, knees, interphalangeal joints, wrists, and elbows.⁸⁹ The foot and ankle are involved in 90% of cases. In fact, it is said that the absence of talus involvement in an adult is cause to reject the diagnosis of KBD.⁹⁰ The hand develops enlargement of interphalangeal joints reminiscent of Heberden and Bouchard nodes; however, the middle and distal phalanges are shortened, termed *brachydactyly* (Fig. 185.7 shows a photograph and a radiograph of a hand with KBD), resembling the foreshortened distal and middle phalanges caused by frostbite injury in children.⁹³ The carpal bones, in particular the capitate and hamate, are more likely to be involved with worsening severity of KBD involvement of the hand.⁹⁴ Short stature is one of the main features of the disease, and dwarfism is sometimes marked, involving a disproportionate shortening of the extremities.⁸⁸

Standardized national clinical and radiologic diagnostic criteria for KBD have been available in China since 1995 (clinical GB16003-1995) (Table 185.2) and 2001 (radiologic W/T 207-2001) (Table 185.3); their correlation with other features of KBD, including brachydactyly, has been evaluated.⁹⁵ In addition, other staging systems have been devised for this disorder based on clinical^{64,89,96} or radiologic^{90,91,94} features (see Tables 185.1 and 185.2). A significant correlation has been shown between the clinical classification system of Mathieu⁸⁹ and the radiologic classification system of Hinsen-kamp.⁹¹ Although the clinical criteria are more sensitive, the radiologic criteria are more specific for KBD.⁹¹ An instrument for assessing quality of life has recently been developed and validated for use in KBD patient populations.⁹⁷

Investigations

Noninvasive

The abnormalities of growth and development and the radiographic appearance of this disease have been ascribed to pathologic endochondral growth at epiphyseal and acrophyseal sites.⁹⁸ The radiologic features of KBD have been reported to resemble the lesions of osteochondrosis,⁶⁴ a group of diseases of children and adolescents that are caused by insufficient blood supply to the epiphyses and lead to localized tissue necrosis at the growing ends of bones during the years of rapid bone growth. The radiologic joint features deemed diagnostic of KBD include irregularities of bony margins, sclerosis, and a cone-shaped, fused, or fragmented metaphysis.⁹¹ Several serum and urine OA-related biomarkers have been shown to be associated with the presence or severity of KBD, including chondroitin sulfate and proteoglycan-related epitopes, pyridinoline, serum nitric oxide, CD44, matrix metalloproteinase-1 (MMP-1), interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), cartilage oligomeric matrix protein, and type II collagen.⁹⁹⁻¹⁰² Proteomic studies comparing KBD and control sera are ongoing to identify diagnostic biomarkers for KBD.^{103,104}

Fig. 185.7 Kashin-Beck Disease of the hand. (a) Photograph of a hand with the brachydactyly of Kashin-Beck disease (on left) compared with a reference hand of a Chinese individual without Kashin-Beck disease (on right). (b) Radiograph of the hand of an individual with Kashin-Beck disease demonstrating shortened middle and distal phalanges, cone-shaped metaphyses, and “pumice stone” deformity of carpal bones. (a, Courtesy Dr. Junling Cao; b, courtesy Dr. Xiong Guo.)

Invasive

The initial pathologic change in KBD is necrosis of cartilage and secondary repair and remodeling of cartilages of the metaphyses, bone ends, epiphyses, and carpal bones⁹⁰ leading to disturbed mineralization, impaired skeletal development, disfiguration of joints, and chronic deforming OA.^{96,105} Because the metaphyseal side of the growth plate is the most active site of bone growth and development during childhood, it is the site affected

earliest and most frequently with cartilage necrosis (chondronecrosis).⁹⁰ Apoptotic chondrocytes are found more frequently in KBD than in control cartilage¹⁰⁶ and at a rate comparable to that in OA. The histologic features of KBD lesions have included the absence of vascularization within the proximal cartilage endplate.¹⁰⁷ *In vitro* studies of cartilage or chondrocytes have demonstrated increased hydroxyproline content, decreased thermal stability of collagen II, and increased levels of precursor collagen (procollagen II) thought possibly due to inhibition of conversion to the mature

TABLE 185.2

Staging systems for Kashin-Beck disease

Clinical staging system based on the Chinese National Criteria					
Stage	Signs				
Early	Flexion of the terminal part of the fingers or crooked fingers and arthritis pain in knee and ankle joints without enlarged finger joints				
First stage	Enlarged finger joints and clinical symptoms of the early stage				
Second stage	Shortened fingers and clinical symptoms of the first stage				
Third stage	Retarded growth or dwarfism and clinical symptoms of the second stage				
Clinical staging system of Mathieu					
Stage	Age	Joint enlargement (due to metaphyseal widening)	Joint pain	Severity of motion restriction of most affected joint	Associated symptoms*
I	<15 yr	–	+	Grade 0	–
I	All ages	+	–	Grade 0	–
II	All ages	+	+	Grade 1-2	–
III	All ages	+	+	Grade 1-2	+
Clinical staging criteria of Beck					
Stage	Severity	Joint pathology	Joint pain	Range of motion	Other findings
I	Mild	Deformation/thickening of fingers 2-4	+ (AM and with activity)	Slight limitation of interphalangeal and fine crepitation of larger joints (elbow, knee, ankle)	–
II	Moderate	Deformation/thickening of all fingers, elbow, knee, ankle, wrist, and 1-2 large joints; brachydactyly	+	Limited wrist motion and finger extension	Intraarticular loose bodies, muscle atrophy
III	Severe	Marked deformation/thickening of finger joints; distinct brachydactyly	+	Unable to make a fist; very limited motion or fused large joints	Platypodia (splayfoot); short/deformed sole

**Associated symptoms are tiredness, muscle weakness, inability to work, pes planus, waddling gait, and dwarfism.
Data for Chinese National Criteria–based staging system from document GB16003-1995 in [reference 154](#); data for Mathieu staging system from [reference 89](#); data for Beck criteria (1906) from [reference 62](#).*

TABLE 185.3

Radiologic staging systems for Kashin-Beck disease

Radiologic staging system based on the Chinese National Criteria			
Grade	Basis for grade (features scored below)		
Normal	0 points		
Mild	1-4 points		
Moderate	5-7 points		
Severe	8-10 points		
Possible points	Radiologic features		
3	Osteophyte: absent = 0; <2 mm = 1; 2 to <4 mm = 2; ≥4 mm = 3		
3	Joint space narrowing: absent = 0; narrowed by >½ normal joint space = 1; <½ normal joint space but joint surfaces did not contact = 2; joint surfaces contacted or loose bodies found in the joint = 3		
1	Sclerosis of bony margins: absent = 0; present = 1		
1	Depression of bony margins: absent = 0; present = 1		
1	Transverse deformation of joint: absent = 0; present = 1		
1	Cysts under bony articular surface: absent = 0; present = 1		
Radiologic staging system of Hinsenkamp*			
Grade	Radiologic feature	Total score	Stage
Grade 0	No radiologic change	0	0
Grade 1	Radiologic changes of the epiphysis or metaphysis	1-10	I
Grade 2	Radiologic changes of the epiphysis or metaphysis without fusion	11-20	II
Grade 3	Local fusion of the metaphyseal growth plate	21-36	III

**In the Hinsenkamp system, six sites (hands/wrists, elbows, shoulders, ankles, knees, and hips) are graded on the 0-3 scale yielding a total score of 0-36 and then a stage of disease is assigned. Data for Chinese National Criteria–based staging system from document WS/T 207-2001 in [reference 154](#); data for Hinsenkamp staging system from [reference 91](#).*

collagen II,⁶⁵ as well as decreased collagen II levels; increased levels of collagens I, II, and X; increased MMP-13 levels^{108,109}; and increased aggrecanase-mediated proteoglycan loss from cartilage.¹⁰¹ These effects were ascribed to fulvic acid toxicity and possibly other environmental exposures.

Differential diagnosis

Selenium and iodine deficiency are linked geographically. Distinguishing between the radiologic features of hypothyroidism and KBD can be difficult.⁷¹ It has been thought possible that some of the musculoskeletal abnormalities of KBD may be related to thyroid dysfunction early in life,⁷⁶ because hypothyroidism in children is associated with epiphyseal dysgenesis, delay of bone development, and reduced endochondral ossification. Of note, selenium plays an indispensable role in thyroid hormone synthesis because it is required for iodothyronine deiodinase activity that converts thyroxine to triiodothyronine.⁸⁵ Thus a closer examination of the role of thyroid hormone abnormalities in the pathogenesis of KBD would appear to be warranted.

Pathogenesis

To date, no consensus has been reached on the cause of KBD. Early residents of the Urov River Valley associated it with “bad” drinking water and had a notion that the disease could be passed down from generation to generation in “diseased families.”⁶² Three causal mechanisms have been proposed to interact to cause KBD: a deficiency in trace elements (selenium and iodine),¹¹⁰ the presence of organic matter in drinking water (fulvic and humic acid produced by chemical and microbial decomposition of plants and animals),^{69,75} and contamination of food by noxious mycotoxins.¹¹¹⁻¹¹³ Cold exposure and occupational microtrauma have also been implicated in disease severity.⁹² In this model, low selenium level is an essential but insufficient condition for the development of KBD.⁶⁹ It is posited that free radicals, generated by mycotoxins and fulvic acid or other environmental factors, damage chondrocytes under conditions of inadequate antioxidant defense, iodine deficiency, and possible protein-calorie malnutrition.⁶⁷ Inadequate antioxidant defense derives from a lack of selenoprotein antioxidants such as glutathione peroxidase and thioredoxin reductase. Selenium can partially counteract adverse chondral effects of the fungal toxin T-2¹¹⁴ and IL-1,¹¹⁵ and suppression of the selenoprotein iodothyronine deiodinase-2 (responsible for conversion of thyroid hormone to its active form) results in strong proinflammatory effects with increased expression of inflammatory mediators, IL-1 β , and cyclooxygenase-2 (COX-2).¹¹⁶ These results underscore the key antiinflammatory role performed by selenium in cartilage. In the absence of adequate selenium and antioxidant defense, the final common pathway of pathogenesis is necrosis of the hypertrophic chondrocytes at the base of the articular and growth plate cartilages.¹¹⁷

Selenium is necessary for the growth of cells in tissue culture⁸⁴ and is commonly used (in the form of selenite) as a supplement for chondrocyte culture in combination with insulin and transferrin.¹¹⁸ Selenium bioavailability ultimately depends on both intestinal absorption of selenium and its conversion into a biochemically active form.¹¹⁹ Selenomethionine is 50% more bioavailable than selenite.¹²⁰ Brief (24-hour) exposure of chondrocytes *in vitro* to selenomethionine (0.5 to 1.0 $\mu\text{mol/L}$) has been shown to block IL-1-mediated inhibition of cartilage matrix macromolecule (collagen II, aggrecan) synthesis and transforming growth factor- β 2 receptor synthesis,¹²¹ as well as induced nitric oxide synthase and COX-2 expression and nitric oxide and prostaglandin E₂ production.¹¹⁵

Some chondrotoxic effects and other pathologic effects have been attributed to mycotoxins and fulvic acid. Nivalenol, a mycotoxin produced by *Fusarium*, inhibits protein synthesis by binding to the ribosome. Added to cartilage grafts *in vitro*, nivalenol inhibits glycosaminoglycan synthesis and retention in the extracellular matrix, overall reducing the chondroitin sulfate content of cartilage.^{122,123} It has been hypothesized that mycotoxins may inhibit angiogenesis,⁹¹ block thyroid hormone function,⁶⁷ and bind thyroid receptors in bone cells.⁶⁷ When added to the diet of rats, fungal extracts inhibit glutathione peroxidase and superoxide dismutase activities and accelerate lipid peroxidation.⁹¹ Similarly, it is hypothesized that organic matter in the form of fulvic acid may accumulate in musculoskeletal tissues and induce superoxide production via its semiquinone radicals¹²⁴ and lipid peroxidation.¹²⁵ These, in turn, would be poorly scavenged in a selenium-deficient host with low levels of glutathione peroxidase activity. *In vitro*, fulvic acid stimulates the generation of H₂O₂ by chondrocytes and increases collagen secretion in a H₂O₂-dependent manner.¹²⁶ Fulvic acid has also been shown to inhibit the conversion of procollagen II to mature collagen II.⁶⁵ However, the levels used in these experiments have not been equated to blood or tissue levels of affected individuals in endemic areas. Finally, this

family of organic acids may interfere with selenium absorption from the intestine.¹²⁷

Genetics

As described earlier, hyposelenosis may be necessary but not sufficient to cause disease. Within the low-selenium belt in China, there are some places and individuals without KBD even though selenium concentrations in the soil, food grains, and hair are low.^{128,129} The mosaic character of disease prevalence (affected villages next to healthy ones) was noted as early as 1939.⁶² In his extensive review of the KBD literature from 1849 to 1992,⁶⁴ Allander noted instances in which Chinese villages where KBD was endemic were within 30 to 50 miles of villages where KBD was nonexistent. This suggests that other environmental or as yet unknown genetic factors are required for full manifestation of the syndrome. Clustering within families has been noted.^{67,117} Genetic factors, common environmental risk factors, or a combination of both could account for this clustering. A 2006-2007 survey of 212 case and 212 control families (total of 3848 individuals) reported that use of river water as the main source of drinking water clustered in KBD families and accounted for a sixfold increase in the odds of KBD.⁷⁵ The proportion of KBD-affected relatives among the probands' families was substantial and significantly higher than that in the control families (55.4% versus 10.2%, respectively; $P = .0001$).⁷⁵ Neither drinking river water alone nor other dietary factors fully explained the familial aggregation of KBD. In a companion study, the heritability of KBD was estimated to be 29% in Linyou County, Shaanxi, China.¹³⁰ These observations suggest that other factors influence the development of disease. Nevertheless, until recently the possibility of a genetic component of disease susceptibility has generally been overlooked in favor of environmental risk factors. Given the association of selenium deficiency with KBD, the possibility of genetic variation in the regulation of selenium absorption and metabolism has been of interest. It is estimated that there are 25 selenoproteins in the human genome.^{84,131} Several of these selenium-containing proteins have known and crucial functions *in vivo*: glutathione peroxidase protects tissues against reactive oxygen damage; iodothyronine deiodinase converts thyroxine to the biologically active form, 3,4,3'-triiodothyronine¹²⁴; and selenoprotein P, produced primarily in the liver,¹²⁰ plays a key role in whole-body selenium metabolism⁸⁴ and carries 60% to 70% of the circulating selenium.¹³² Moreover, selenoprotein P is a negative acute-phase protein,¹³² leading possibly to further limitation of selenium bioavailability during periods of acute illness and thus possibly potentiating KBD. To date, genes reported to contain genetic variants associated with KBD have included *HLA-DRB1*,¹³³ *TNF- α* ,¹³⁴ glutathione peroxidase 4 (*GPX4*),¹³⁵ and glutathione peroxidase 1 (*GPX1*).¹³⁶ Preliminary association analysis of one polymorphism in selenoprotein P (*SEPP1*) yielded negative results.¹³⁷

Animal models

Mice fed for two generations on a selenium-deficient diet supplemented with fulvic acid in the drinking water demonstrated disturbed development of the articular space and meniscus, disturbed subchondral ossification, overly hydroxylated collagens I and II with less thermal stability, and low bone formation activity.^{124,138} Second-generation rats fed a selenium-deficient diet showed growth retardation, a reduction in pituitary growth hormone and plasma insulin-like growth factor I levels, and impaired bone metabolism and osteopenia.¹³⁹ Chronic selenium deficiency in rats was also associated with abnormalities of chondrocytes in the deep cartilage layers consisting of nuclear degeneration and ballooning of the endoplasmic reticulum.¹⁴⁰ Combined selenium and iodine deficiency in rats significantly impaired the growth of bone and cartilage.¹⁴¹ Rats developed chondronecrosis when fed a selenium-deficient diet for 2 months followed by a 1-month oral challenge with bacterial A-1 toxin (from a bacterial contaminant of local grain).¹⁴² Conversely, mice prone to OA (the STR/IN strain) were protected from disease while on a diet enriched with vitamins (C, E, A, and B₆) and selenium.¹⁴³ The role played by muscle in this disease has also been questioned. Severe white muscle lesions develop in sheep in response to low selenium levels. Therefore the possibility has been raised that muscle weakness may contribute directly to the musculoskeletal abnormalities of KBD.⁶⁴

Strong support for a definitive role of selenium deficiency in KBD has recently been provided by a mouse model in which the gene encoding the selenocysteine transfer RNA, essential for selenoprotein expression, has been deleted from chondrocytes.¹⁴⁴ The mice manifested a number of pathologic features typical of KBD (chondronecrosis of articular cartilage, ear cartilage, and tracheal cartilage; small spine size; disproportionate widening of the epiphyseal growth plates) and died by 7 weeks of age due to respiratory distress from tracheomalacia.

TABLE 185.4
Methods of selenium supplementation for populations in China

Form of selenium	Dose or concentration
Sodium selenite (oral)*	1 mg/wk for children aged 3-10 yr 2 mg/wk for children aged 11-13 yr
Selenized table salt	16.7 mg/kg salt, which provided a calculated average intake of 50 µg selenium/day
Sodium selenite (fertilizer spray)	15 g/hectare

*Representative of the most common selenium dosage regimen of the clinical trials performed to date in China for Kashin-Beck disease per Zou et al.⁶⁶ The U.S. recommended daily allowance of selenium for adults is 70 µg/day for men and 55 µg/day for women. Adopted from references 64, 66, and 120.

Management

Individuals with radiologic lesions have more advanced stages of the disease and are expected to be less influenced by selenium treatment than individuals without radiologic lesions.¹¹⁰ Therefore the key to managing KBD is to prevent its occurrence. The strategy of selenium supplementation is considered the mainstay of therapy for KBD in China. Daily intakes of selenium below 20 µg are considered insufficient.¹³² The U.S. RDA is based on optimization of plasma glutathione peroxidase concentrations; however, the amount of selenium needed to optimize selenoprotein P levels may be greater than the current U.S. RDA.¹²⁰ The plasma selenium concentration is often used to assess selenium nutritional status. At plasma concentrations of about 0.08 mg/L (0.4 µmol/L), the selenoproteins glutathione peroxidase and selenoprotein P are considered optimized.¹²⁰ Selenium supplementation in China has been effected through the distribution of selenium-enriched table salt, the distribution of selenium tablets to children,⁷³ and the use of selenium-enriched fertilizer.^{64,74} (Table 185.4). Selenomethionine, the major form of selenium found in food, has almost twice the bioavailability of selenium in the form of selenite.¹²⁰ The use of selenium-enriched fertilizer in selenium-deficient areas has been shown to increase the average daily intake of selenium as much as fourfold to 16.8 µg/day.⁷⁴ Two meta-analyses have summarized the results of the known trials of selenium supplementation for KBD performed to date (5 randomized, 10 nonrandomized), conducted in China from 1982 to 1994.^{66,145} These trials involved more than

2000 participants ranging in age from 0 to 16 years with 10 months to 6 years of follow-up. Based on radiographic and physical examination outcomes (national KBD criteria), selenium reduced the odds of initial KBD manifestations by 80% (odds ratios of 0.13 and 0.16 for the randomized trials and nonrandomized trials, respectively). Although few of these trials reported adverse effects, one trial that administered 1 to 2 mg/day (rather than per week) for the first week reported nausea and vomiting at the beginning of the trial. Excess selenium is toxic, so dosages must be carefully regulated. Both selenium-deficient and selenium-excess diets have adverse effects on the mechanical properties of bones.¹⁰³ Other toxic effects of selenium excess include hair and nail loss,¹⁴⁶ neurologic dysfunction and respiratory distress,¹⁴⁷ and death.⁷² The toxicity limit is estimated to be 600 to 800 µg/day.^{132,146}

In KBD-affected areas of Tibet, where both selenium and iodine deficiency are endemic, supplementation of iodine over 12 months was primarily responsible for stimulating the growth of a population of 10-year-old children.¹¹⁰ As described earlier, a 12-month study of Tibetan children showed the beneficial effects of supplementing iodine in cases of KBD associated with both iodine and selenium deficiency. Because selenium repletion may aggravate hypothyroidism,¹¹⁰ iodine must be administered before selenium in cases in which both are deficient.¹¹⁰ This study has suggested the importance of iodine deficiency as an etiologic factor for KBD manifestations in some areas. In this study, new radiologic lesions occurred only in the group given placebo and iodine group and not in the group given both selenium and iodine, which suggests a potential role for selenium therapy as well.

Other preventive efforts include providing better storage of crops, drying corn, shifting to other crops less susceptible to fungal contamination and with greater bioavailability of selenium (e.g., from corn to rice),^{64,91} and improving the quality of drinking water.⁶⁵ Standard treatments for OA, including physical therapy, nonsteroidal antiinflammatory agents, glucosamine, and intraarticular hyaluronan, can also be of benefit in cases of established KBD.¹⁴⁸⁻¹⁵¹ Some individuals undergo osteotomy¹⁵² or extraction of loose bodies and joint lavage by arthroscopy,¹⁵³ but currently joint replacement is uncommon due to cost barriers.

Acknowledgments

CRYSTAL-RELATED ARTHROPATHIES

186

Epidemiology of gout

■ HYON K. CHOI

- In most current societies, with abundantly available food and a strong tendency toward a sedentary lifestyle, gout has changed in epidemiology from a "disease of kings" to a "disease of commoners."
- A number of epidemiologic studies from a diverse range of countries consistently suggest that gout has increased in prevalence and incidence in the last few decades and has become the most common inflammatory arthritis.
- Purine loading and insulin resistance are two key mediating mechanisms underlying the action of many modifiable lifestyle risk factors for gout.
- Lifestyle modifications for gout should consider both the associated benefits and risks in a holistic manner because gout is often associated with many cardiovascular-metabolic comorbid conditions and sequelae.
- Reducing adiposity with daily exercise and limiting intake of red meat and sugary beverages help reduce uric acid levels, risk for gout, insulin resistance, and comorbid conditions, whereas dairy products, vegetables, nuts, legumes, fruits (less sugary ones), and whole grains are healthy dietary choices for patients with gout.

HISTORICAL PERSPECTIVE

Gout is an inflammatory arthritis caused by the crystallization of uric acid within joints and is associated with hyperuricemia. Once known as a "disease of kings and king of diseases," gout has affected figures such as Alexander the Great, Charlemagne, Henry VIII, Emperor Charles V, Benjamin Franklin, Alexander Hamilton, Tennyson, Coleridge, Voltaire, Isaac Newton, Charles Darwin, and Leonardo da Vinci.¹ Also described by Hippocrates during the Golden Age of Greece, gout was previously considered a disease of the affluent and observed primarily in middle-aged men of the wealthy upper class ("the patrician malady").¹⁻³ As is appreciable in these historical descriptions, gout had often afflicted the wealthy and the educated, particularly those who not only could afford the comforts of life but also enjoyed its excesses with lifestyles that bordered on overindulgence, gluttony, and intemperance.¹ As these lifestyles have become affordable and prevalent among the general public in the modern era, particularly in Western societies with abundantly available food and a strong tendency toward a sedentary lifestyle, gout has changed in epidemiology from a "disease of kings" to a "disease of commoners."

WESTERNIZATION AND GOUT TRENDS

Humans are the only mammals in which gout is known to develop spontaneously, probably because hyperuricemia commonly develops only in

humans.^{1,4} In most fish, amphibians, and nonprimate mammals, the uric acid generated from purine metabolism undergoes oxidative degradation via the enzyme uricase, which produces the more soluble compound allantoin.⁴ The impact of diet on uric acid levels in species that lack uricase may also provide insight into why serum uric acid levels in the great apes¹ (1.5 to 3.0 mg/dL) are substantially lower than those in humans in the modern era (6.1 mg/dL in men in the U.S. general population).⁵ The great apes primarily consume vegetables and fruit, and their animal protein intake is minimal.¹ Early humans in indigenous scavenging and gathering societies who lived on traditional diets primarily derived from vegetables and fruits with sporadic additions of fish and game probably had serum uric acid levels similar to those of the great apes.¹

A number of epidemiologic studies from various countries suggest that the prevalence of gout has increased in the last few decades.⁶ This increase is probably explained by trends in lifestyle factors associated with westernization.^{4,7} For example, since the introduction of Western culture and dietary habits, gout has become epidemic among some native peoples, such as the Maori of New Zealand.^{1,8,9} After the introduction of a diet high in fatty meats and carbohydrates and low in dairy products in the early 1900s, an epidemic of obesity and gout developed.^{1,8,9} Three similarly conducted serial surveys in New Zealand showed an increase in the prevalence of gout in both European, U.S., and Maori descendants (Table 186.1).⁸⁻¹⁰ Findings from the United States, United Kingdom, and China also suggest that the disease burden of gout is similarly increasing (see Table 186.1).⁸⁻¹⁸

Correspondingly, gout was rare among blacks in Africa, especially in rural areas where traditional agricultural and dairy-based diets were common, but its frequency has been increasing, particularly in urban communities.¹ Gout was considered rare in African Americans in the early 1900s, but changes in diet have led to the rapid development of obesity, diabetes, and hypertension. Today, mean serum uric levels are higher and gout is more common in African Americans than in whites.^{1,19} Furthermore, ecologic studies of Japanese and Filipino populations have found that U.S. immigrants from these countries had increases in serum uric acid levels, the incidence of gout, or both in comparison to their nonmigrant counterparts.¹

CASE DEFINITIONS IN GOUT EPIDEMIOLOGY

Epidemiologic estimates of the disease burden of gout (e.g., prevalence or incidence) depend on case definitions, as with any other condition. Definitive diagnosis of gout requires either the presence of monosodium urate monohydrate crystals in joint fluid or the presence of tophi.²⁰ However, in population surveys designed to estimate the prevalence of gout, this method of identification is impractical. For this reason, several gout case definitions have been developed, including self-reports, the Rome criteria, the New York criteria, and the American College of Rheumatology (ACR) preliminary criteria.²⁰⁻²² For example, the prevalence of gout has been estimated from self-reported data derived from various years of the U.S. National

†Lifetime prevalence of gout obtained by asking the question "Has a doctor ever told you that you had gout?"
ACR, American College of Rheumatology (formerly American Rheumatism Association); GP, general practice; NHANES, National Health and Nutrition Examination Survey.

Health Interviews Surveys. Data from the Sudbury study showed that 44% of self-reported cases could be validated according to the Rome or New York criteria.²³ However, the validation rate from a physician cohort (Johns Hopkins Precursor Study) was much higher—80% according to the ACR survey criteria applied by mail and 100% by mail combined with medical record review.²⁴ Similarly, the validation rate of self-reported gout in a recent large prospective cohort of male health professionals was approximately 70% according to the ACR survey criteria assessed by a mailed survey.²⁵ The difference in the validation rates of self-reported gout between these studies probably reflects differences in the level of general health knowledge in the study populations.

PREVALENCE OF GOUT

Estimates of prevalence from various countries and time frames, along with their definitions of gout, are summarized in Table 186.1. The latest lifetime prevalence of self-reported gout (diagnosed by health professionals) in the United States was estimated in 2007-2008 to be 3.9% of U.S. adults, which translates into 8.3 million individuals.⁵ This prevalence increased with age to 9.3% of U.S. adults older than 60 years (4.7 million). This recent prevalence estimate is significantly higher than the 1988-1994 estimate (2.7%, an absolute difference of 1.2%).⁵ Furthermore, the prevalence of

hyperuricemia and mean serum urate levels in 2007-2008 were significantly higher than the 1988-1994 estimates. Similarly, serial U.S. National Health Interview Surveys that used the same survey instrument showed that the annual prevalence of gout doubled between 1969 and 1996 and that the steepest increase occurred between 1969 and 1976 (see Table 186.1).^{5,26} U.K. studies based on general practice diagnostic indices found similarly increasing prevalence estimates of gout between the 1970s¹¹ and 1990s¹³ (see Table 186.1).
Studies conducted in the UK-General Practice Research Database in 1999¹⁴ and the IMS Disease Analyzer from 2000 to 2005¹⁵ both found the prevalence of gout to be 1.4%. A Taiwanese Nutrition and Health Survey conducted during the mid-1990s found a prevalence similar to that in the United States (3.4%).¹⁸

INCIDENCE OF GOUT

Several prospective cohort studies have estimated the incidence of gout.⁶ The Johns Hopkins Precursors Study documented 60 cases of self-reported incident gout in 1216 male physicians observed over a median of 29 years (incidence, 1.73 per 1000 patient-years).^{6,27} The Health Professionals Follow Up Study monitored 47,150 male health professionals for 12 years and identified 730 cases of incident gout (incidence, 1.50 per 1000 patient-years according to the ACR survey criteria²⁰).²⁵ The Framingham Heart Study monitored 5209 people for a median of 28 years and documented 104 incident cases of gout (diagnosed clinically by typical symptoms and medications) in women and 200 cases in men for incidence rates of 1.4 and 4.0 per 1000 person-years, respectively.²⁸
Serial investigations of computerized medical records from the Rochester Epidemiology Project showed that the incidence of gout in individuals not exposed to diuretics (using the ACR survey criteria²⁰) more than doubled from 20.2 per 100,000 in 1977/1978 to 45.9 per 100,000 in 1995/1996, whereas the proportion of gout associated with diuretic use decreased significantly during that period.²⁹
Two studies of general practice databases in the United Kingdom estimated the incidence of gout (physician recorded) in the 1990s and 2000s. The first, based on data from 1990 to 1999, found that the incidence of gout ranged from a low of 119 cases per 100,000 patient-years in 1991 to a high of 180 cases per 100,000 patient-years in 1994.¹⁴ The second study, which was based on data from 2000 to 2007, found that the mean annual incidence of gout was 268 per 100,000 patient-years. Both studies reported that the incidence of gout was higher in men than in women and increased with age regardless of sex.³⁰

RISK FACTORS FOR HYPERURICEMIA AND GOUT

It has been well established that hyperuricemia is the causal precursor in the development of gout. Population studies show a direct positive (linear to exponential) relationship between serum urate levels and future risk for gout.⁴ Conversely, effective management of hyperuricemia prevents gout.⁴ Thus, this section summarizes the risk factors for hyperuricemia and gout together.

Demographics: sex, age, and ethnicity

Serum urate concentrations in men average about 1 mg/dL higher than in women in adult life, which is probably due to increased renal urate clearance by estrogen in women. This leads to a substantially higher risk for gout in men than in women, particularly before menopause.³¹ A Japanese study showed that combined use of estrogen and progesterone resulted in a significant drop in serum uric acid in postmenopausal hyperuricemic women whereas no drop occurred in controls.³² A U.S. nationwide study found that menopause was associated with increased serum uric acid levels and postmenopausal hormone replacement therapy with decreased uric acid levels,³³ and a prospective study showed consistent findings with the risk for incident gout in 92,535 women.³⁴
Age appears to have an influence only in women, in whom serum uric acid levels steadily increase with age.³⁵ In the aforementioned U.S. nationwide study, the increase attenuated substantially after adjusting for menopausal status but remained significant, thus suggesting that menopause explains a substantial portion, but not all of the age-associated increase in women.³³ The remaining age-associated increase was explained by other age-related factors such as declining renal function, diuretic use, and hypertension.³³

Fig. 186.1 Impact of lifestyle factors on risk for gout and their implications within a healthy eating plate. Directional arrows and blue font information are specific to gout and are not found in the original healthy eating plate. Upward red arrows denote an increased risk for gout, whereas downward green arrows denote a decreased risk. Horizontal green arrows denote no influence on risk for gout. Striped green arrows denote a potential effect, but without prospective evidence for the outcome of gout. References on the relationship between diet and risk for gout are listed in Table 186.2. (Adapted from <http://www.hsph.harvard.edu/nutritionsource/healthy-eating-plate/>.)

Serum uric acid levels appear to vary by race or ethnicity. African Americans have higher serum uric acid levels than white Americans do,¹⁹ which has been linked to the increased prevalence of hypertension in the former.³⁶ In addition, serum uric acid levels are higher in certain aboriginal people such as the Maori³⁷ and Taiwanese³⁸ aborigines.

Lifestyle factors

Gout is a metabolically driven arthropathy that can be controlled substantially through lifestyle modifications. The following sections review the epidemiologic evidence on modifiable lifestyle risk factors for gout, as well as their implications for general health (Fig. 186.1).

Adiposity

Adiposity is one of the strongest risk factors for hyperuricemia and gout. Prospective cohort studies have consistently found a strong relationship between higher adiposity (or weight gain) and increased risk for both hyperuricemia and incident gout.^{27,28,39-41} A recent study also documented that weight reduction leads to a considerable decrease in serum urate levels.⁴² Similarly, in the Swedish Bariatric Surgery Outcome study, gastric surgery–induced weight reduction was associated with substantially lower odds for the development of hyperuricemia.⁴³ Finally, men who have lost weight have shown a significantly lower risk for incident gout.⁴⁰ Adiposity probably increases uric acid levels both by decreasing renal excretion of urate and by increasing urate production.⁴⁴⁻⁴⁶

Meat and seafood

Meat intake (particularly red meat) contributes to an increased risk for gout,²⁴ probably because its high purine content raises urate levels, as demonstrated by short-term metabolic experiments of purine loading in animals and humans.^{24,47,48} Furthermore, red meat is a key source of saturated fat, which is associated with increased insulin resistance, which in turn reduces renal excretion of urate.⁴⁹ Indeed, higher consumption of meat is associated with hyperuricemia,⁵⁰ and men in the highest quintile of meat intake were found to have a 41% higher future risk for gout than men in the lowest quintile (Table 186.2, and see Fig. 186.1).*

Seafood intake (including fish and shellfish) can also increase the risk for gout²⁵ through its high purine content despite not being associated with increased insulin resistance like red meat. Men in the highest quintile of seafood intake were found to have a 51% higher risk for gout than those in the lowest quintile.²⁵ Furthermore, a prospective Internet-based case-crossover study of 633 gout patients showed that purine intake from animal sources was associated with up to a 2.4-fold increased risk for recurrent gout.⁷⁵

Dairy intake

A large prospective study showed that men in the highest quintile of dairy intake had a 44% lower risk for gout than did men in the lowest quintile. When dairy intake was stratified by fat content, the protective association persisted with low-fat dairy consumption but became null with high-fat dairy consumption.²⁵ Consistently, dairy consumption was found to be inversely associated with uric acid levels.⁵⁰ Furthermore, recent randomized trials have shown that intact milk intake has an acute urate-lowering effect⁷⁶ and that skim milk powder derivatives may have antiinflammatory effects against acute gout flares.⁷⁷ Thus, dairy products may exert their urate-lowering or antiinflammatory effects without the concomitant purine load contained in other animal protein sources such as meat and seafood.^{76,78}

Purine-rich vegetables, vegetable protein, and cherries

Contrary to traditional dietary approaches, consumption of purine-rich vegetables was not found to be associated with risk for incident gout (see Table 186.2 and Fig. 186.1).²⁵ Correspondingly, individual purine-rich plant food items such as nuts, legumes, spinach, mushrooms, oatmeal, and cauliflower were not associated with risk for gout. Men in the highest quintile of vegetable protein consumption actually showed a 27% lower risk for gout than did the lowest quintile.²⁵ Furthermore, the short-term impact of purine from plant sources on risk for recurrent gout attacks was found to be minimal.⁷⁵ These findings may be explained by insufficient amounts or bioavailability of purine in these plant food items²⁵ and by other healthy constituents (fiber or healthy fat) that may reduce insulin resistance and risk for gout.⁷⁹

The aforementioned study of preexisting gout patients also found that cherry intake over a 2-day period was associated with a 35% lower risk for gout attacks than was no intake.⁸⁰ Although previous small studies suggested urate-lowering or antiinflammatory effects of cherries or associated anthocyanins, these findings call for confirmation.⁸⁰

Alcoholic beverages

Increasing alcohol intake was found to be associated with increasing risk for gout in a dose-dependent manner.⁵² Among different types of alcoholic beverages, beer had the largest impact.⁵³ A nationwide study showed the same pattern of associations with uric acid levels.⁵³ Similarly, the aforementioned study of preexisting gout patients also confirmed that alcohol consumption triggers recurrent gout attacks in gout patients.⁸¹

Alcohol can induce hyperuricemia, probably through both increased urate production⁸² and decreased urate excretion. Ethanol administration can increase uric acid production by increasing degradation of adenosine triphosphate (ATP) to adenosine monophosphate (AMP), a uric acid precursor.⁸² Decreased urate excretion occurs via conversion of alcohol to lactic acid, as well as the confounding effects of fasting-induced acetoacetic and β -hydroxybutyric acidemia, which both reduce renal uric acid excretion by competitively inhibiting uric acid secretion by the proximal

tubule.^{83,84} Furthermore, among individual alcoholic beverages, beer has a high purine content, which is predominantly guanosine, a readily absorbable nucleoside.^{83,85}

Sugar-sweetened sodas and fructose-rich foods

The doubling of the prevalence^{5,26} and incidence²⁹ of gout over the last few decades in the United States has coincided with a substantial increase in soft drink and fructose consumption.^{54,55} Furthermore, two large cohort studies found that consumption of sugar-sweetened soft drinks and fructose is associated with increased risk for gout in both sexes (see Table 186.2 and Fig. 186.1).^{54,55} In contrast, diet soft drinks were not associated with risk for gout. Other major contributors to fructose intake such as sugary fruit juice or fructose-rich fruits (i.e., apples and oranges) were associated with a modestly increased risk for gout in men⁵⁴ but not in women.⁵⁵ Correspondingly, serum urate levels were found to increase with increasing intake of sugar-sweetened soft drinks, whereas diet soft drink consumption was not associated with increased serum urate levels.⁵⁶ Furthermore, added sugar intake was also associated with increased serum urate levels.⁵⁷

Fructose intake can raise serum urate levels by increasing the degradation of ATP to AMP, thereby prompting activation of the pathway of purine degradation to uric acid.^{53,86} Furthermore, fructose intake is associated with increased serum insulin levels and insulin resistance⁸⁷ and could therefore indirectly increase serum urate levels and risk for gout.

Coffee, tea, and caffeine

Coffee consumption may lower serum uric acid levels and risk for gout in the long term via various mechanisms.^{59,88} For example, caffeine (1,3,7-trimethylxanthine) is a methylxanthine and may be a competitive inhibitor of xanthine oxidase.^{88,89} Long-term intake of coffee and caffeine may also lower insulin levels⁹⁰ and increase insulin sensitivity.⁹¹ Japanese studies and a U.S. nationwide study found that serum uric acid levels decreased with increasing coffee intake.⁶⁰⁻⁶² Furthermore, coffee consumption was associated with a decreased risk for gout in men⁵⁹ and women,⁸⁸ whereas tea intake was

not associated with hyperuricemia or risk for gout in either sex.^{59,88} A modest inverse association was also found for decaffeinated coffee.^{59,88}

Vitamin C

Randomized trials have demonstrated a urate-lowering effect of vitamin C via its uricosuric properties.^{64,65} Supplementation with 500 mg/day of vitamin C for 2 months was shown to reduce serum urate levels by 0.5 mg/dL. Several observational studies from Taiwan⁹² and the United States^{66,67} have extended evidence of an inverse link between vitamin C intake and risk for hyperuricemia or incident gout.

Medications and lead exposure

Several commonly used medications can affect serum uric acid levels and potentially the risk for gout, including aspirin, fenofibrate, diuretics, female hormones, and antihypertensives.⁴ A study found that low doses of salicylate (75, 150, and 325 mg daily) decreased uric acid excretion (by 1.35, 0.85, and 0.65 mL/min) and increased serum uric acid levels (by 0.27, 0.21, and 0.04 mg/dL, respectively).⁹³ Similarly, fenofibrate was found to have urate-lowering benefits in addition to its primary lipid-lowering effects.⁴

Certain antihypertensive medications also increase serum uric acid levels and thus may contribute to risk for gout. For example, beyond the well-known phenomena of diuretic-induced hyperuricemia and gout, β-blockers have been shown to increase serum uric acid levels in short-term trials.^{4,94} Conversely, calcium channel blockers and losartan have been found to lower serum uric acid levels^{4,94} and therefore have the potential to lower the risk for gout. Compatible with these urate-affecting properties, a recent population-based study revealed that calcium channel blockers and losartan were associated with a lower risk for incident gout in individuals with hypertension (see Table 186.2).⁶⁸ In contrast, diuretics, β-blockers, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers other than losartan were associated with increased risk for gout.⁶⁸

Even though chronic lead intoxication is known to cause hyperuricemia and gout (i.e., saturnine gout), recent study findings suggest that

low-level exposure to lead is also associated with an increased prevalence of hyperuricemia and gout.⁶⁹ A U.S. community-based cohort study found a positive association between the long-term accumulation of lead (contained in bone) and uric acid levels⁷⁰; however, no such association with risk for gout was evident at the levels arising from community exposure.

Key mediating mechanisms of lifestyle factors: purine and insulin resistance

As discussed earlier, both purine loading and insulin resistance are key mediating mechanisms underlying the actions of adiposity and many lifestyle factors on gout. Traditional lifestyle approaches to prevent gout have almost exclusively focused on purine-loading risk factors. However, factors that increase insulin resistance and thus decrease renal excretion of urate can increase uric acid levels and risk for gout.⁴⁹ Furthermore, because insulin resistance syndrome is highly prevalent in patients with gout or hyperuricemic^{41,71,95} and has cardiovascular-metabolic consequences,^{72,96-99} it is important to consider factors that can affect insulin resistance, particularly in long-term lifestyle recommendations.

Cardiovascular-metabolic conditions and other disorders

Many medical conditions can elevate serum uric acid levels and risk for gout, including cardiovascular-metabolic conditions, renal disorders, and other conditions associated with severe tissue hypoxia, such as proliferative and inflammatory disorders associated with increased cell turnover.⁸ Recent epidemiologic studies have quantified the potential impact of medical conditions on the risk for incident gout, including hypertension, renal insufficiency,^{40,41} ischemic heart disease, hyperlipidemia, and psoriasis.³⁰ Although these conditions are associated with an increased risk for gout, type 1 or 2 diabetes is associated with a decreased risk for gout,⁷³ probably through the uricosuric effect of glycosuria or the impaired inflammatory response associated with diabetes (see Table 186.2).⁷⁴

Beyond the potential excess risk for gout brought on by these other medical conditions, gout and hyperuricemia are metabolic conditions associated with multiple cardiovascular-metabolic comorbid conditions and complications.^{72,96-99} These comorbidities of gout and independent risks for adverse cardiovascular outcomes and premature mortality provide a strong rationale for serious consideration of these issues when determining appropriate lifestyle approaches for patients with gout (see Fig. 186.1).

Etiology and pathogenesis of gout

■ LACHY McLEAN ■ NICOLA DALBETH

- Gout (monosodium urate crystal deposition disease) is an inflammatory arthritis resulting from the deposition of monosodium urate crystals from extracellular fluids saturated with urate, the end product of human purine metabolism.
- Acute gout is a severe but self-limited arthritis caused by the inflammatory response to urate crystals. Repeated acute attacks and persistent crystal deposition can lead to chronic arthropathy and deforming tophaceous gout.
- Hyperuricemia is a serum urate concentration exceeding approximately 6.8 mg/dL ($\approx 400 \mu\text{M}$) and reflects the tissue urate saturation that is the central biochemical precursor for gout.
- Defects in purine metabolic enzymes (such as hypoxanthine-guanine phosphoribosyltransferase and 5-phosphoribosyl 1-pyrophosphate synthetase 1) are well-characterized causes of gout with urate overproduction but account for less than 1% of cases of gout. Large genetic studies have revealed many candidates involving urate transport, metabolic pathways, and regulation of inflammation. The known genes still explain only a minority of the strong heritability of hyperuricemia and gout.
- In most patients with gout, hyperuricemia results from relative impairment of renal uric acid excretion, often exacerbated by dietary excess, diuretics, and alcohol. Variation in one or more of the proximal tubular urate transporters (such as GLUT9 and URAT1) also contributes to hyperuricemia.
- Acute gouty inflammation is initiated by resident synovial cells, including phagocytes, which secrete chemokines and cytokines to attract and activate the neutrophils that predominate in acute gout.
- Activation of the NLRP3 inflammasome by monosodium urate crystals and the resultant release of mature interleukin-1 β are central to initiation of acute gouty inflammation.
- Joint damage in chronic gout is strongly linked to intraarticular tophi, with activation of catabolic pathways leading to cartilage and bone degradation.

Gout is a painful and potentially destructive rheumatic disorder that arises in the setting of hyperuricemia, a condition defined by saturation of serum with urate. Urate is the obligatory end product of human purine metabolism. The clinical manifestations of gout arise as a consequence of urate or uric acid crystal deposition and include acute gouty arthritis, chronic gouty arthropathy, tophi, renal functional impairment, and urolithiasis (kidney and bladder stones). This chapter focuses on the articular manifestations of gout.

URATE PHYSIOLOGY

Gout is the result of inflammatory responses to crystals deposited because of one or more derangements in the physiology of urate. In contrast to most mammals, urate is the final oxidative degradation product of purine metabolism in humans and higher primate species because the gene encoding the enzyme uricase (urate oxidase) has been silenced by mutations.¹ Urate is the most abundant natural antioxidant in the human body (Table 187.1). The traditional view has been that a major physiologic role of urate is to remove reactive oxygen species, thereby possibly providing protection

against oxidant-induced neurologic and cardiovascular degenerative processes. However, administration of pegloticase, which leads to dramatic reductions in urate concentrations, did not result in increased lipid or protein oxidation, thus suggesting that urate is not a major factor controlling oxidative stress *in vivo*.²

Urate may also have an important role in immune surveillance. Distressed and dying cells produce locally high urate concentrations as a “danger” signal, which acts as an endogenous adjuvant to help trigger inflammatory and both innate and specific immune responses (discussed in more detail later).³ Urate may also have had an evolutionary role in maintenance of blood pressure and intravascular volume.⁴

Forms of uric acid

Uric acid ($\text{C}_5\text{H}_4\text{N}_4\text{O}_3$; 2,6,8-trioxypurine) is a weak organic acid ionized at position 9 with a functional $\text{pK}_{\text{a}1}$ in serum of 5.75. Urate exists in biologic systems in two forms with limited solubility (Fig. 187.1). At the 7.4 pH of most body fluids, urate ion levels exceed those of un-ionized uric acid in a ratio of approximately 50:1. Because of the high concentration of sodium in extracellular fluid, urate functions mainly as monosodium urate (MSU). As a consequence, the high solubility of the urate ion (120 mg/dL, 7 mM) is replaced by the much lower solubility of MSU ($\approx 6.8 \text{ mg/dL}$ or $400 \mu\text{M}$).

Serum urate concentrations exceeding 6.8 mg/dL are saturating, a condition referred to as *hyperuricemia*. Persistent hyperuricemia reflects saturation of extracellular fluid with urate. Increasing levels of hyperuricemia impart increasing (but not linearly related) risk for urate crystal deposition and the associated clinical consequences.⁵ Hyperuricemia is very common and affects more than 20% of adult white males in the United States⁶; it is even more common in certain ethnicities. Even though hyperuricemia most often does not evolve into clinical gout, it is associated with several highly prevalent chronic disorders, as discussed in Chapter 186.

In acidic body fluids, nonionized uric acid predominates. For example, at pH 5.0 (common in urine), the solubility of uric acid is only approximately 10 to 15 mg/dL (≈ 600 to $900 \mu\text{M}$), a range often exceeded in the urine of normal, as well as gouty, individuals. This explains the formation of uric acid crystals and stones in the urinary tract, in contrast to MSU monohydrate crystals, which are deposited in joints, tophi, renal interstitium, and other tissues of gouty patients.

Urate balance

The diet contains little urate, and dietary urate is poorly absorbed. Ingestion of other purines, endogenous synthesis of purines from small-molecule nonpurine precursors, and reutilization of preformed body purine compounds are more important sources.⁷ Purines other than urate are more abundant in foods and beverages and can, along with dietary nonpurine components (discussed later), contribute significantly to purine disposition (Box 187.1).^{8,9}

Nevertheless, the bulk of urate is usually derived from endogenous synthesis, which occurs mainly in the liver with a smaller contribution by the small intestine. The urate released from cells circulates relatively free (<4%) of serum protein binding,⁷ so all or nearly all circulating urate is filtered at the glomerulus.

Under steady-state conditions, urate production is balanced by uric acid disposal, largely through renal excretion (equivalent to about $\frac{2}{3}$ of daily production), as discussed below. Urate secretion into the small intestine, with breakdown of urate by gut bacteria (intestinal uricolysis), accounts for nearly all the rest of urate disposal. The body pool of urate is expanded in hyperuricemic states resulting from urate overproduction or impaired disposal.

■ TABLE 187.1

Factors influencing hyperuricemia and gout

Dietary influences*		Clinical associations		Drugs	
Chemical composition	Total caloric intake (obesity, leptin)	Age		Induce or worsen hyperuricemia or precipitate acute gout	Aspirin (low dose) Chemotherapeutic cytotoxics Diuretics (especially thiazides) Ethambutol Tacrolimus
	Triglycerides	Male or postmenopausal female			
Specific food examples	Carbohydrates (insulin)	Direct causal link	X chromosome-linked enzyme defects		
	Protein (aspartate, glutamine, glycine)		HPRT deficiencies:		
	DNA (cellularity, nucleus-cytoplasm ratio)		Complete (Lesch-Nyhan syndrome)	Urate-lowering or antihyperuricemic	Allopurinol, oxypurinol, febuxostat
	RNA (transcriptional activity, messengers)		Partial (Kelley-Seegmiller syndrome)	xanthine oxidase inhibitors	
	Red meat†		PRPP synthetase overactivity		
	Beer		Autosome-linked enzyme defects		
	Liver		Glucose-6-phosphatase deficiency		
	Shellfish		Fructose-1-phosphate aldolase deficiency		
	Thymus, pancreas		Myogenic glycogenoses (types III, V, VII)	Uricosuric agents	Ethanol Benzbromarone, probenecid, lesinurad, sulfapyrazone, losartan, fenofibrate, leflunomide, calcium channel blockers
	Yeast extracts		Uromodulin-associated kidney disease		
Associated with lower urate level	Fructose		FJHN		
	Sugar-sweetened drinks		MCKD types 1 and 2		
Associated with lower urate level	Low-fat dairy products		Hemolytic disorders		
	Cherries		Hemopoietic malignancies; tumor lysis		
	Vitamin C		Lactic acidosis or ketoacidosis; hypoxemic states		
			Lead nephropathy, chronic low-level exposure		
			Preeclampsia‡	Uricase preparations	rasburicase, pegloticase
			Renal impairment§		
			Systemic inflammatory conditions (including psoriasis)		
			Vasopressin-resistant diabetes insipidus		
			Bartter, Gitelman, Down syndromes		
			Hypothyroidism; hyperparathyroidism	Other mechanisms	Sevelamer Effects of lactate on transporters
Associated with lower urate level			Hypertiglyceridemia		
			Hypertension		
			Hypothyroidism		
			Obesity		
			Cardiovascular disease		
			Aggressive introduction of hypouricemic therapy	Role of alcohol	Direct renal tubular effect by ethanol?
			Alcohol or shellfish binges		Hypertension
			Sepsis, myocardial infarction, acute severe illness		Adenosine triphosphate turnover
			Sudden cessation of hypouricemic therapy		Guanosine content (beer)
			Trauma, surgery, dehydration, parenteral nutrition		Poor compliance with therapy

*In addition to the direct contributions of dietary purines and protein as uric acid precursors, diet can adversely influence renal urate excretion. The renal actions of insulin, leptin, and other systemic factors may mediate some of these effects.

†Intake of purine-rich vegetables is not associated with gout.

‡Hyperuricemia is a sensitive indicator of both effective volume status and tubular dysfunction.

§Uremia appears to blunt the inflammatory response to urate crystals, so gout is less common than might be expected for a given degree of hyperuricemia in patients with advanced renal dysfunction.

*A causal relationship has not been established with the associated disorders (see text).

FJHN, familial juvenile hyperuricemic nephropathy; HPRT, hypoxanthine-guanine phosphoribosyltransferase; MCKD, medullary cystic kidney disease; PRPP, 5-phosphoribosyl 1-pyrophosphate.

URIC ACID AND THE URATE ANION

Fig. 187.1 At physiologic pH (7.4), urate predominates at about 50:1 over unionized uric acid. Urate ion solubility is functionally reduced at the high sodium concentration of extracellular fluids, so monosodium urate and uric acid have relatively low solubility in biologic fluids.

BOX 187.1 PHYSIOLOGIC FUNCTIONS OF PURINES

- Antioxidation (urate)
- Nucleotide building blocks for nucleic acids (DNA and RNA)
- Nucleotide components of coenzymes (e.g., coenzyme A, flavin adenine dinucleotide [FAD], nicotinamide adenine dinucleotide [NAD])
- High-energy phosphate donors in enzyme reactions (e.g., adenosine triphosphate [ATP])
- Metabolic regulators (e.g., cyclic adenosine monophosphate [AMP], cyclic guanosine monophosphate [GMP])
- Neurotransmitters
- Extracellular messengers (e.g., adenosine, ATP)
- Intracellular second messengers (e.g., G protein-coupled receptors)
- Immunologic adjuvants, endogenous "danger" signal for innate immunity
- Maintenance of extracellular volume, vascular tone (urate) (hypothesized)

Urate pools in normal men range from about 800 to 1500 mg and in women from 500 to 1000 mg. Daily turnover of the body's urate pool (balanced production and disposal) is considerable and averages 60% to 70% of the pool (0.5 to 1 g) every day. Urate saturation of extracellular fluids (for which hyperuricemia is a surrogate marker) predisposes to urate crystal formation and deposition, events required for clinical expression of gout.

Serum urate concentrations in children are lower than those in adults. During male puberty, values increase into the adult male range. Serum urate levels remain lower in women of reproductive age than in their male counterparts.¹⁰ This gender difference results mostly from the action of estrogens,¹¹ which alter the activity of key renal urate transporters. This results in less renal tubular uric acid reabsorption and thus increased urate clearance in women.

With the onset of menopause, serum urate values in women increase and approach or equal those of men. This physiologic change in women is partly reversed by estrogen-containing hormone replacement therapy and is accompanied by increases in the incidence of hyperuricemia and, over the succeeding 2 to 3 decades, gout.

HYPERURICEMIA

Conditioning factors

Several genetic and physiologic circumstances predispose all humans to the development of hyperuricemia and gout: the species-wide deficiency of uricase, the enzyme catalyzing the conversion of uric acid to the much more soluble excretory product allantoin; net reabsorption of 90% of the urate filtered at the glomerulus; and the limited solubility of both uric acid and MSU in body fluids.

Despite these conditioning factors, most people do not display the sustained hyperuricemia that reflects extracellular fluid saturation, and MSU crystal deposition disease develops in even fewer. The many processes influencing the development of hyperuricemia (Fig. 187.2; also see Table 187.1) operate through impaired renal uric acid excretion (most commonly), excessive urate production, or a combination of these two mechanisms.¹²

With increased urate production or decreased renal uric acid excretion, intestinal uricolytic increases to as much as half of the total urate disposal. In contrast, when intestinal urate excretion is impaired, the kidneys are confronted with a higher urate load.⁷ The transporter ABCG2 (ATP-binding cassette sub-family G, member 2) plays a central role in intestinal urate transport.¹³

Fig. 187.2 The systemic urate pool and the likelihood of gout are determined by the dynamic balance between dietary purines, endogenous synthesis and recycling, and disposal by the kidney and gut. ABCG2, ATP-binding cassette sub-family G member 2; ATP, adenosine triphosphate; URAT1, urate transporter 1; GLUT9, glucose transporter 9; NPT, sodium-dependent phosphate cotransporter.

Classification of hyperuricemia

Hyperuricemia and gout may arise in individuals with or without an underlying clinical disorder or toxic or drug exposure. When a specific process resulting in hyperuricemia is identifiable, it is said to be *secondary* (see Table 187.1). When no such process is evident, the hyperuricemia is termed *primary* or idiopathic. Several diseases, toxic states, and medications lead to hyperuricemia as a result of urate overproduction. Foremost among these are diseases associated with cellular proliferation and destruction, such as acute leukemias and lymphomas, tumor lysis syndromes, hemolytic states, and psoriasis.

The causes of hyperuricemia have traditionally also been divided into *overproduction* causes (mainly consisting of metabolic factors) and *underexcretion* causes (mostly renal). Many patients with gout have a combination, with relative urate underexcretion by the kidneys contributing the most. Analysis of the role of ABCG2 in intestinal handling of urate has challenged the conventional concept of overproduction-induced hyperuricemia.¹³ ABCG2 knockout mice have reduced intestinal urate excretion, which leads to higher serum urate levels. Despite also lacking ABCG2 in the kidneys, renal urate excretion in this situation is still higher than normal, thus indicating that other transporters in the kidney can partially compensate.

Urate overproduction may be better described as a type of “renal overload,” which in turn consists of the subtypes *extrarenal underexcretion* and *genuine urate overproduction*.¹³

PURINE METABOLISM: PATHWAYS AND REGULATION OF URATE PRODUCTION

Purines are compounds that possess a nine-member purine nucleus composed of fused pyrimidine and imidazole rings. Purines fulfill essential functions in all living cells (see Box 187.1). Most functions of purines are carried out by nucleotide and nucleoside derivatives of the purine bases adenine, hypoxanthine, and guanine. Representative structures of purine bases, nucleosides, and nucleotides are shown in Figure 187.3.

Purine synthetic pathways

The sole sources of new purines in the body are the diet and endogenous synthesis of purines from nonpurine precursors. The dietary contribution to urate production and turnover is significant. Removal of purines from the diet of normal individuals for 10 days can reduce serum urate levels by 25% and urinary uric acid excretion by as much as 50%.

However, purine-free or heavily purine-restricted diets are unpalatable and require substitution by potentially atherogenic dietary components to maintain caloric balance. Severe dietary purine restriction is seldom successful as a first line of therapy for the hyperuricemia of gout. On the other hand, diets high in fructose, meat, and fish content,¹⁴ as well as beer and distilled alcohol intake,¹⁵ promote hyperuricemia and increase the risk for gout, whereas vitamin C and cow's milk may reduce the risk.

The biochemical pathways of purine metabolism and their regulation are discussed in more detail elsewhere.¹⁴ The only endogenous pathway of net purine production (Fig. 187.4) is called purine synthesis *de novo* and involves 10 steps. The purine ring is synthesized on a backbone of ribose-5-phosphate donated by the key regulatory substrate *5-phosphoribosyl 1-pyrophosphate* (PRPP) from the pentose phosphate sugar pathway. The end product of this pathway is the nucleotide *inosine monophosphate* (IMP). IMP serves as a branch point in the conversion of new purines into the adenylate and guanylate classes of purine nucleotides or, alternatively, into the purine degradation pathway culminating in urate formation.

Purine synthesis *de novo* is an energy-costly process. Considerable saving in cellular energy expenditure is achieved by an extensive network of reactions that interconvert and salvage purine nucleotides, nucleosides, and bases. This saves energy and provides flexibility in the provision of specific purines for a wide array of cellular functions.

Degradation of purines to urate

Degradation of purine nucleotides and nucleosides to purine bases culminates in the key urate precursors *hypoxanthine* and *guanine*. They are mostly reused in salvage reactions with PRPP, catalyzed by the enzyme *hypoxanthine-guanine phosphoribosyltransferase* (HPRP). The remainder of guanine is deaminated to *xanthine*. Unsalvaged hypoxanthine is oxidized to xanthine, which undergoes further oxidation to urate. The enzyme *xanthine oxidoreductase* (XOR) catalyzes the conversion of both hypoxanthine to xanthine and xanthine to urate.

Fig. 187.3 Purine ring atoms are numbered 1 to 9, as shown in the upper left panel. Pentose sugar carbon atoms are numbered 1' to 5', as shown in the lower left panel. In purine *nucleosides*, a purine base is joined to a pentose ring through an N-glycoside bond between the purine 9 and pentose 1' atoms. *Nucleotides* are phosphate esters of the nucleoside that contain one, two, or three phosphate groups (nucleoside monophosphate, diphosphate, or triphosphate, respectively) attached at the 5' carbon of the sugar. *Nucleotidases* remove phosphate groups. *Phosphorylases* remove both the phosphate groups and the sugar. *Kinases* transfer a high-energy phosphate group (usually donated by ATP). The nucleoside of hypoxanthine is known as inosine, and the respective nucleotide is inosine monophosphate. dATP, deoxyadenosine triphosphate.

Fig. 187.4 The gene for uricase (urate oxidase) has been inactivated in humans and other primate species such that urate is the end product of purine metabolism. Intermediates and enzymes not pertinent to hyperuricemia and gout have been omitted for simplicity ("10 steps"). ADA, adenosine deaminase; AMP, adenosine monophosphate; AMPD, AMP deaminase; APRT, adenine phosphoribosyltransferase; ATP, adenosine triphosphate; GMP, guanosine monophosphate; GTP, guanosine triphosphate; HPRT, hypoxanthine-guanine phosphoribosyltransferase; IMP, inosine monophosphate; ND, 5'-nucleotidase; PNP, purine nucleoside phosphorylase; PRPP, 5-phosphoribosyl 1-pyrophosphate; XMP, xanthosine monophosphate; XO, xanthine oxidase (oxidoreductase).

XOR is a molybdenum-pterin and iron sulfide cluster-containing flavo-protein that exists in interconvertible forms: an *oxidase* form (xanthine oxidase, XO) which uses oxygen (O_2) to convert hypoxanthine and xanthine to urate; and a *dehydrogenase* form (XDH), which uses the nucleotide oxidized nicotinamide adenine dinucleotide (NAD^+).

The catalytic events in purine base conversion involve binding and oxidation of the substrate (the purine base) at the active site of the oxidase form of XOR. This is accompanied by reduction of molybdenum from valence +6 to +4 by electrons donated by the purine. These electrons are then transferred to the iron sulfide cluster and then to the flavin center. Reoxidation of the flavin moiety by O_2 is accompanied by release of the product (xanthine, urate), including generation of the reactive metabolites H_2O_2 and superoxide ($O_2^{\bullet-}$).

Inhibition of XOR activity is the major action of the class of agents most commonly used for lowering urate levels in patients with gout.¹⁵ Other roles for XOR have also been proposed—protection from infection and tissue injury (because of the generation of unstable oxygen radicals) during and after ischemia.

Purine nucleotide synthesis and degradation are both carefully regulated processes. The major purine synthetic steps targeted by regulation are (1) synthesis of PRPP in the PRPP synthetase (PRS) reaction and (2) use of PRPP in the first step of purine synthesis *de novo* in the amidophosphoribosyltransferase (ATase) reaction (Fig. 187.5).¹⁴ ATase is allosterically inhibited by purine nucleotide products of the pathway and activated by PRPP.¹⁶

When this antagonistic control mechanism malfunctions, increased cellular levels of PRPP result in accelerated purine nucleotide and urate production. This occurs in two rare X chromosome-linked disorders: deficiency of the salvage enzyme HPRT and overactivity of PRS1.¹⁴ Similarly, excessive cellular adenosine triphosphate (ATP) depletion (for example, with tissue hypoxia or acute alcohol intoxication) can lead to reduced inhibitory nucleotide concentrations and consequent urate overproduction. Other states of excessive urate production in patients with gout are not as well characterized at the pathway level. They are likely to involve disruption of the regulatory mechanism for the antagonistic interaction of PRPP and purine nucleotides on amido-PRT.

Fig. 187.5 Rates of the 10-step *de novo* pathway of purine nucleotide synthesis (vertical arrows) are regulated by activity of the enzyme amidophosphoribosyltransferase (ATase), which catalyzes the first step. ATase activity is allosterically controlled by the antagonistic interaction of pathway purine nucleotide products that inhibit (–) the enzyme and the regulatory substrate PRPP that activates (+) amido-PRT. Purine nucleotides also inhibit (–) PRPP synthetase, the enzyme catalyzing the synthesis of PRPP. Regulation directed at these sequential reactions provides a flexible means of controlling purine nucleotide production in an economic manner, a process potentiated by preferential single-step salvage of preformed purine bases in reactions with PRPP catalyzed by the phosphoribosyltransferase enzymes HPRT and APRT (depicted by the curved arrows). APRT, adenine phosphoribosyltransferase; ATP, adenosine triphosphate; HPRP, hypoxanthine-guanine phosphoribosyltransferase; PRPP, 5-phosphoribosyl 1-pyrophosphate; Rib-5-P, ribose-5-phosphate.

RENAL URIC ACID EXCRETION

Models of renal uric acid handling

Despite nearly complete filtration of urate at the glomerulus, clearance of uric acid in adults averages only 5% to 10% that of creatinine clearance, which reflects net renal tubular reabsorption of about 90% of the filtered urate. A four-compartment model for renal uric acid handling has been proposed (Fig. 187.6). This model incorporates glomerular filtration and three proximal tubular processes: urate reabsorption, secretion of reabsorbed urate, and postsecretory reabsorption.

Urate transporters

GLUT9

Molecular and genomic approaches have identified several transporters involved in renal uric acid excretion, including some with substantial specificity for urate.¹⁷ Two of these transporters, glucose transporter 9 (GLUT9) and urate transporter 1 (URAT1), are members of the organic acid transporter (OAT) family and have strong effects on serum urate levels.

GLUT9 is the product of the *SLC2A9* gene. It is a voltage-driven urate transporter that mediates urate reabsorption from the tubular cell to the circulation. In humans, GLUT9 exists in two isoforms: GLUT9L, identified on the basolateral aspects (“blood” side) of the proximal renal tubular epithelial cell, and GLUT9S, located on the apical (“urine”) side.^{18–20} As with URAT1, mediation of urate reabsorption by GLUT9 is inhibited by the uricosuric agents probenecid and benzbromarone.

GLUT9 is also expressed in the basolateral membrane of hepatocytes and regulates serum urate concentrations through dual roles in urate handling in the kidney and uptake in the liver.²¹ Mice with systemic “knockout” of *GLUT9* have moderate hyperuricemia, massive hyperuricosuria, and early-onset nephropathy. In contrast, specific inactivation of the *GLUT9* gene in the liver of adult mice leads to severe hyperuricemia and hyperuricosuria, but without the renal disease.²¹

GLUT9 also transports the sugars glucose and fructose, which may be pertinent to the dietary influences of these compounds on hyperuricemia and gout. A substantial role for GLUT9 in the physiologic regulation of serum or plasma urate levels is further suggested by the results of genome-wide association and candidate gene studies. Such studies show that the *SLC2A9* locus and certain polymorphisms are associated with an increased risk for hyperuricemia and gout.^{22,23} Different mutations of *SCL2A9* have also been linked with renal *hypouricemia*, particularly in patients with intact URAT1.²⁰

URAT1

URAT1 is encoded by the *SLC22A12* gene and has a typical OAT structure.²⁴ URAT1 is highly specific for urate. It mediates the exchange of urate for a variety of endogenous and drug anions known to affect renal uric acid transport. URAT1 can transport urate in either direction across the tubular cell membrane, depending on the relative concentrations of urate and other ions on each side of the membrane. Like GLUT9S, URAT1 localizes to the apical brush border membrane of proximal tubular epithelial cells.

People with mutations in the *SLC22A12* gene (resulting in decreased URAT1 activity) have hypouricemia and hyperuricosuria, as well as exercise-induced renal functional impairment.²⁵ This suggests that URAT1 is important in the renal regulation of serum urate levels in normal individuals.²⁴ The uricosuric drugs probenecid, benzbromarone, and lesinurad increase urate excretion by inhibiting URAT1 and other OATs.^{24,26} Urate transporters may also play other roles in urate metabolism, for example, in the transport of urate across hepatic cell membranes.

URAT1 interacts with the scaffolding protein PDZK1. PDZ motifs are typically involved in the protein-protein interactions that support intracellular signaling and are also present in other urate transporters, including OAT4 and NPT1 (discussed later). This suggests that a more extensive multiprotein complex (the “urate transportosome,” which contains transport and transport regulatory molecules, hormone receptors, and intracellular signaling elements) may be involved in regulated bidirectional transport of urate across the renal tubular epithelial cell. Fractional renal excretion of urate ($FE_{ur} = \text{uric acid clearance/creatinine clearance} \times 100$) in URAT1 knockout mice²⁷ remains substantially less than 100%. This confirms that there are multiple mechanisms of uric acid reabsorption.

Other urate transporters

Many urate transporters are known. ABCG2 functions in both the kidney and intestine, and dysfunction is associated with hyperuricemia and gout.²⁸ The *sodium-dependent phosphate cotransporters* types 1 and 4 (NPT1 and NPT4; encoded by *SLC17A1* and *SLC17A3*, respectively) are located at the

Fig. 187.6 The upper panel illustrates renal uric acid movement as historically divided into four physiologic compartments: glomerular filtration, tubular reabsorption, tubular secretion, and a second round of “postsecretory” reabsorption. The existence of a discrete fourth compartment of postsecretory reabsorption for fine-tuning of net uric acid excretion was controversial, and the anatomic correlates of these four compartments were uncertain. This classic model has declined in significance as the mechanisms underlying renal uric acid handling have become better understood at a molecular level (see text and lower panel). The lower panel indicates some of the key players in reabsorption and secretion of urate across the proximal tubule epithelial cell. Exchange of uric acid for other anions is mediated by specialized channels and transport proteins embedded in the tubular cell membrane. URAT1 and glucose transporter 9 (GLUT9) are significant contributors to uric acid absorption (such that defective function is associated with hypouricemia), whereas ABCG2, sodium-dependent phosphate cotransporter 1 (NPT1), and NPT4 are associated with net uric acid excretion. Uric acid transport is driven in part by a pH gradient produced by active sodium/hydrogen ion exchange. Several other organic acid transporters (OATs) have been implicated in uric acid transport. Transporters may be linked with each other and with regulatory and signaling elements by the PDZK1 scaffolding proteins making up the urate transportosome. Many of the drugs and endogenous mediators that affect renal uric acid disposition interact with these proteins; for example, the uricosuric drugs probenecid, benzbromarone and lesinurad inhibit uric acid reabsorption by URAT1.

luminal membrane of the proximal tubule and mediate net tubular urate secretion.²⁹

The relative importance of the many other OATs and exchangers in human renal urate handling is also uncertain. For example, OAT4, encoded by *SLC22A11* and localized at the apical membrane of the proximal tubules, is also associated with serum urate levels,³⁰ and OAT10 is a secondary target for the uricosurics probenecid and lesinurad.

IMPAIRED RENAL URIC ACID EXCRETION IN GOUT

Most people with hyperuricemia resulting from impaired renal uric acid excretion have normal amounts of uric acid in urine but selectively reduced

uric acid clearance.^{12,31} Excretion of “normal” amounts of uric acid is accomplished by gout patients only when serum urate levels are 2 to 3 mg/dL (120 to 180 μ M) higher than in healthy people excreting the same amount of uric acid. The hyperuricemia that results from this is the prime risk factor for the development of gout. Many mechanisms contribute to net urate excretion. It seems unlikely that a single mechanism for renal hyperuricemia explains the majority of primary renal gout.

Regulation of urate excretion

Renal uric acid processing has been further elucidated by molecular and genetic analyses such as those used to evaluate the role of variants in the GLUT9 and URAT1 transporters in gout patients and as determinants of serum urate or renal uric acid excretion in normal individuals. Alterations

in urate movement may be due to changes in the transporter itself, to changes in associated proteins or ion cotransporters, or to regulation of transport function.

Potential endogenous regulators of urate transport include insulin, leptin, adiponectin, and estrogens. In addition, the likelihood that renal urate transport normally regulates serum urate levels^{24,25,32} suggests that new classes of uricosuric agents acting with more selective action on particular urate transporters or associated molecules could emerge as targeted treatments.

Familial juvenile hyperuricemic nephropathy and medullary cystic kidney disease

Additional insight into uric acid handling has been provided by studies of familial juvenile hyperuricemic nephropathy (FJHN) and medullary cystic kidney disease (MCKD). These autosomal dominantly inherited disorders are characterized by early onset of hyperuricemia (with or without gout), hypertension, and progressive tubulointerstitial inflammation and fibrosis. This culminates in end-stage renal disease, often by 40 years of age.

Most families with FJHN show mutation in the chromosome 16p13-p11 *UMOD* gene,³³ usually affecting exons 4 and 5, which encodes cysteine-rich regions³⁴ of uromodulin, long known as Tamm-Horsfall urinary glycoprotein. More than 60 different *UMOD* mutations have been described. Uromodulin is an abundant disulfide bond–rich urinary protein with several putative proinflammatory and antioxidant properties. It is hypothesized to play a role in maintaining the structural and functional integrity of the ascending loop of Henle by forming a protective gel-like lattice that coats the luminal (urine) side of the tubule.

Mutant uromodulin accumulates in the endoplasmic reticulum. Defects in the protective lattice alter solute fluxes and thereby reduce reabsorption of Na⁺ and Cl[−]. This results in a contracted extracellular volume and compensatory enhancement of sodium-dependent urate transport in the proximal tubule.³⁵

Disorders resembling FJHN and MCKD type 2 at the clinical level have been associated with mutations in other genes, including the preprorenin signal peptide and the *HNF1B* gene.^{36,37}

URATE CRYSTAL FORMATION

Formation of MSU crystals requires sustained high (supersaturated) concentrations of urate. Crystal formation is influenced by many other factors, including the presence of particulate seed nuclei such as cartilage debris, collagen, chondroitin, and hyaluronate released by joint trauma or osteoarthritis (OA); local cation concentrations; pH, temperature, and dehydration; and the balance between macromolecular inhibitors and promoters of crystal formation (Table 187.2).³⁸ IgG and IgM may also aid crystal formation and growth in gout patients.^{39,40} MSU crystals preferentially form at certain sites, particularly the first metatarsophalangeal joint, midfoot, and Achilles tendon.⁴¹

Mounting evidence suggests a link between the presence of OA and sites of MSU crystal deposition.⁴² A cadaveric study reported that urate crystals were nearly always located within or adjacent to OA cartilage lesions.⁴³ A joint with OA has increased levels of cartilage degradation products, such as chondroitin sulfate, which lowers urate solubility and promotes the nucleation and growth of urate crystals.^{44–46}

One reason why gout does not develop in most persistently hyperuricemic people may lie in individual variation in the propensity for forming crystals. However, microscopic and imaging studies have shown that many people with asymptomatic hyperuricemia have evidence of urate crystals within joints,⁴⁷ thus suggesting that crystals may be present within the joint for long periods without eliciting an overt inflammatory response leading to the development of gout.

THE INFLAMMATORY RESPONSE TO URATE CRYSTALS

An acute gout attack occurs when urate microcrystals interact with host cells to initiate an inflammatory response (Fig. 187.7). The crystals triggering the acute gout flare are most likely shed from small preexisting synovial tophi rather than being freshly formed *in situ*. Whether crystals initiate clinically significant inflammation depends on multiple factors, including crystal size, the proteins and other molecules coating them, and the cells that they first encounter. *In-vitro* and animal model data suggest that urate crystals can activate the inflammatory response through several pathways.

■ TABLE 187.2

Gout promoters and inhibitors

Crystal formation	Seed nucleus (particulate) Immunoglobulin Phagocytes Low temperature Low pH Cation concentration Intraarticular dehydration Other (unknown) macromolecules
Triggering the acute flare (local factors)	Rapid change in urate level Microcrystal release IgG coat (apolipoproteins B, E inhibitory) Complement activation (classical, alternate, MAC) Inflammasome activation Cytokine and chemokine release Endothelial activation (e-selectin, ICAM-1, VCAM-1) Local trauma?
Presence of susceptible phagocytes, mast cells (systemic events)	Surgery, trauma Infections, other intercurrent systemic illness Alcohol, dietary intake Drugs that raise or lower circulating urate level

A diverse array of proteins and other mediators have been identified on the surfaces of urate crystals. In addition to their proinflammatory effect through opsonizing existing crystals, IgM and IgG antibodies may promote crystal formation by providing a stable molecular platform for crystal nucleation and growth. Apolipoproteins are the best characterized of the antiinflammatory molecules that coat crystals. The characteristics of the phagocytes encountering the crystals may be crucial; macrophages that are more differentiated are less likely to elicit proinflammatory cytokines. ICAM-1, intercellular adhesion molecule 1; MAC, membrane attack complex; VCAM-1, vascular cell adhesion molecule 1.

Which pathway predominates *in vivo* in acute gouty inflammation is uncertain.

In acute gout the predominant inflammatory cell in synovial fluid and the synovial membrane is the neutrophil, and activation of neutrophils seems to contribute the bulk of the proinflammatory stimulus. However, healthy joints do not contain a significant resident population of neutrophils. Urate crystals have their initial interaction with cells normally resident in the tissue.^{48,49}

The resident macrophages within the synovial membrane play a central role in instigating and driving the initial inflammatory response to urate crystals within the joint. Other cells such as synovial fibroblasts, antigen-presenting dendritic cells (DCs), eosinophils, and mast cells may also play a role in the initiation phase of acute gouty inflammation.

Crystal phagocytosis

Despite potent proinflammatory potential, urate crystals do not necessarily trigger acute inflammation. Gout patients and healthy hyperuricemic individuals may have urate crystals in clinically uninvolved joints. Heavily crystal-laden fluids (“urate milk”) are sometimes found in relatively uninfamed bursae and joints. The dense masses of urate crystals in tophi can reach massive dimensions, often with little apparent inflammatory response. In confined spaces such as axial or visceral sites, tophi can enlarge progressively without eliciting symptoms until critical compression of neighboring tissues ensues.

Similarly, patients with intercritical and chronic gout may have prolonged periods with absent or relatively low-grade synovitis despite the ongoing presence of urate crystals in the synovial environment. Thus, for urate crystals to trigger acute inflammation, additional determinants such as crystal size, crystal coatings, the local cytokine milieu, and encounters with particular cell types are necessary.

Microcrystals first need to be released from larger crystals or from tophi (Fig. 187.8). This fits with the clinical observation that gout flares are associated more with rapid changes in urate concentration than with absolute serum urate levels. For example, rapid and large urate reduction with intensive urate-lowering therapy is more likely to precipitate gout flares than a gradual approach. It is thought that rapid reductions in the urate concentration partially redissolve the margins of larger deposits and release fresh microcrystals. Crystal masses located within synovial tophi are surrounded by a protein coat, and dissolution of synovial tophi may serve to expose uncoated crystal surfaces.

Fig. 187.7 Many signals have an impact at critical points in this pathway. Urate crystals do not necessarily form in hyperuricemic patients. Crystals ingested by phagocytes sometimes elicit remarkably little inflammation, and inflammation is often low grade or clinically inapparent in chronic gout, thus indicating robust regulation of the pathways shown. Factors leading to spontaneous termination of an acute gout attack are incompletely understood. Apo-B, apolipoprotein B; IL-1, interleukin-1; MCR, melanocortin receptor; NO, nitric oxide; PPAR- γ , peroxisome proliferator-activated receptor- γ ; TGF- β , transforming growth factor- β ; TNF- α , tumor necrosis factor- α .

Fig. 187.8 Monosodium urate crystals aspirated from a subcutaneous tophus. The crystals are visualized with polarized transmission white (halogen) light, a 90-degree extinction filter, and a 530-nm first-order compensator.

Proteins binding to urate crystals

MSU crystals are composed of a highly ordered, regular array of urate and sodium ions and water molecules. Although the MSU crystal surface has a net negative charge, some positive charges are also exposed. MSU crystal surfaces can bind a variety of lipids, lipoproteins, and proteins,⁵⁰ including immunoglobulin G (IgG), which attaches via both charge interactions and hydrogen bonding. The resulting conformational change in IgG encourages phagocytosis by cells with Fc γ receptors (e.g., Fc γ RIII, CD16).

The complement system is involved in acute gout inflammation at several levels. Crystal-bound IgG activates the classical complement pathway. Urate crystals also activate complement directly through both the classical and alternative complement pathways. These pathways promote further opsonization via deposition of the complement split product C3b on the crystal exterior. C3b decays to iC3b and interacts with complement receptor CR3 (CD11b/CD18).

The soluble complement split products C3a and C5a act as additional chemoattractants. The complement “membrane attack complex” (MAC), which consists of the terminal complement components C5b through C9, may play an important role; rabbits lacking the MAC component C6 have reduced neutrophil responses to urate crystals.⁵¹

Coating of MSU crystals with apolipoprotein can counter the opsonic effects of IgG Fc and complement by decreasing the attractiveness of urate crystals to phagocytes.⁵² Apolipoprotein B (apo-B) is a major component of the serum low-density lipoprotein fraction and can coat crystals to inhibit stimulation of neutrophils. Apo-E has similar effects and can be made locally by synovial macrophages.

Other proteins detected on urate crystal surfaces include further complement activation products, lysosomal enzymes, and the antiinflammatory cytokine transforming growth factor- β (TGF- β). The inflammatory potential of MSU crystals reflects the balance between the proinflammatory and anti-inflammatory elements of this coating.

Phagocyte responsiveness

In addition to crystal size and coating, the host cell making first contact with the crystal is a crucial determinant of the inflammatory response (Box 187.2, Fig. 187.9; also see Fig. 187.7). Synovial fluid phagocytes from gout patients' noninflamed joints often contain urate crystals.⁵³ This indicates that crystals in the synovial compartment do not necessarily elicit overt inflammation despite active engagement with phagocytes.

Immature macrophages and blood monocytes mount a vigorous response to urate crystals. In contrast, more differentiated macrophages that release TGF- β show a greatly reduced proinflammatory mediator response despite equally efficient crystal internalization.⁵⁴ Most phagocytes in “normal” joints are macrophages rather than neutrophils.⁵⁵

Some mature phagocytes residing in human synovium may thus be able to ingest MSU crystals without triggering inflammation, whereas any circumstance that promotes the entry of fresh monocytes or neutrophils into the joint is more conducive to causing an acute gout attack.

THE ACUTE ATTACK OF GOUT

Urate crystals are a potent inflammatory stimulus that have multiple mechanisms for interacting with cells (reviewed elsewhere⁵⁶). The interaction of MSU crystals with phagocytes involves two broad mechanisms that depend on crystal concentration and surface reactivity. First, crystals can activate cells through the “conventional” route as opsonized and phagocytosed particles, analogous to the response seen with phagocytosed microorganisms. This process elicits the stereotypic phagocyte response of lysosomal fusion, respiratory burst, and release of inflammatory mediators.

A second and perhaps predominant mechanism involves the particular properties of the negatively charged MSU crystal surface. Their strong surface reactivity enables MSU crystals to cross-link membrane glycoproteins and directly activate proinflammatory signaling pathways at several levels within the phagocyte. The crystals interact directly with signaling proteins in the cell membrane (see Box 187.2 and Fig. 187.9) and bypass mechanisms that should normally regulate these pathways. Such mechanisms include integrins such as the CD11b/CD18 complex on leukocytes and $\alpha_{IIb}\beta_3$ on platelets, the Fc γ receptor CD16,⁵⁷ CD14, phospholipases, chemokine receptors, and receptor tyrosine kinases.

Although the phagocyte Toll-like receptors TLR2 and TLR4 (important in triggering innate immune responses via the adaptor protein Myd88) may also be involved in urate crystal inflammation, their exact role has been contentious.^{48,58} Certain free fatty acids such as C18:0 appear to synergize

BOX 187.2 INFLAMMATORY EVENTS IN AN ACUTE GOUT ATTACK

- a. Sequence of cellular events
 1. Deposition of urate crystals and release of microcrystals
 2. Proinflammatory coating (e.g., IgG, complement)
 3. Initial interaction with resident cells: tissue macrophages ± fibroblasts, mast cells, others
 4. Activation of membrane signaling molecules (TLR, CD14, TREM)
 5. Release of cytokines, especially IL-1, TNF- α , and chemokines
 6. Activation of endothelial cell adhesion molecules
 7. Emigration, attraction, and activation of neutrophils
 8. Phagocytosis of crystals by neutrophils
 9. Delayed neutrophil apoptosis
 10. Cross-linking of inflammatory signaling proteins
 11. Removal of crystal coating, membrane damage, phagolysosome rupture
 12. Activation of NLRP3 inflammasome, production of active IL-1 and IL-18
 13. Enzyme and mediator release
 14. Resolution—cytokines (e.g., TGF- β), MCR and PPAR- γ ligands, mature macrophages
- b. Membrane mediators
 - Fc γ receptors (Fc γ RIII/CD16)
 - GPCRs (e.g., chemokine receptors)
 - Toll-like receptors (TLR2, TLR4)
 - Complement receptors
 - Integrins
- c. Intracellular signaling
 - NLRP3 inflammasome
 - Tyrosine kinases (Syk, Src, Pyk-2)
 - Mitogen-activated protein kinases (p38, JNK, ERK-1, ERK-2)
 - Downstream TLR pathway (Myd88, IRAK-1, TRAF-6, IK- κ B)
 - Nuclear factors (NF- κ B, AP-1)
 - Lipid kinase PI3K
- d. Soluble mediators released
 - Chemokines: CXCL (e.g., IL-8), CCL (e.g., MCP-1)
 - Complement split products
 - TNF- α
 - Kinins
 - Metalloproteinases
 - Reactive nitrogen species (NO)
 - S100 proteins (S100A8/9; MRP 8/14)
 - TGF- β
 - RANKL
 - IL-1
 - Endothelins
 - IL-6
 - Leukotrienes
 - Reactive oxygen species
 - Prostaglandins
 - Substance P

Urate crystals can activate many cell types and trigger the release of a diverse array of proinflammatory mediators. Multiple pathways have been implicated in different experimental systems and based on the detection of mediators in gout patients, and it is likely that some of these mechanisms operate in parallel. The clinical efficacy of the inhibition of prostanooids and of IL-1 in preventing and reducing the inflammation of acute gout has established their role beyond doubt. Intervention *in vivo* with selective inhibitors of other mediators to “prove” their significance in humans has not been reported, and it is more difficult to be certain of the size of their contribution.

AP-1, activator protein-1; ERK, extracellular signal-regulated kinase; GPCR, G-protein coupled receptor; K- κ B, inhibitor of NF- κ B; IL-1, interleukin-1; IRAK, interleukin-1 receptor-associated kinase; JNK, Jun N-terminal kinase; MCP-1, monocyte chemoattractant protein-1; MCR, melanocortin receptor; MRP, myeloid release protein; NF- κ B, nuclear factor- κ B; NO, nitric oxide; PI3K, phosphatidylinositol 3'-kinase; PPAR- γ , peroxisome proliferator-activated receptor- γ ; RANKL, receptor activator of NF- κ B ligand; TGF- β , transforming growth factor- β ; TLR, Toll-like receptor; TNF- α , tumor necrosis factor- α ; TRAF, TNF receptor-associated factor; TREM, triggering receptor expressed on myeloid cells.

with urate crystals to engage TLR2 and induce release of interleukin-1 β (IL-1 β),⁵⁹ thus suggesting a further potential explanation of gout flares triggered by dietary excess.

Intracellular messengers

Once inside the phagocyte, urate crystals damage the phagosome membrane and hence lead to its rupture. The released phagosome contents then

activate the nucleotide-binding oligomerization domain-like receptor (NLR) NLRP3 inflammasome.⁶⁰ The inflammasome is a multiprotein cytoplasmic complex that senses cell damage and the presence of microbial products. It consists of the sensor protein NLRP3 (also known as cryopyrin and encoded by the *NLRP3* gene) and adaptor proteins CARD8/TUCAN (encoded by the *CARD8* gene) and ASC, which convert procaspase-1 into its active enzyme form.

Caspase-1 then cleaves pro-IL-1 β and pro-IL-18 into their active, inflammation-promoting forms. Release of IL-1 and IL-18 is in turn modulated by interactions between extracellular ATP and purinergic receptors on the cell surface. Further support for the central importance of the inflammasome/IL-1 pathway comes from the efficacy of IL-1 antagonists such as canakinumab and rilonacept in both treating and preventing acute gout flares.

For most external stimuli that activate inflammatory cells, signal transduction from receptors on the cell surface requires a carefully coordinated cascade of tyrosine kinase phosphorylation and interconnections with other messenger systems. MSU crystals can again bypass these “normal” routes and directly activate second-messenger systems.⁶¹

As with other steps in crystal-induced inflammation, multiple intracellular signaling pathways have been implicated (see Box 187.2). It is likely that these pathways operate in parallel. The p38 mitogen-activated protein kinase is a key regulatory point for many of the cytokines implicated in various forms of inflammatory arthritis and is involved in cell activation by MSU crystals.⁶² Both MSU and calcium pyrophosphate dihydrate crystals also activate the kinases Jun N-terminal kinase (JNK), extracellular signal-regulated kinase 1 (ERK-1), and ERK-2.

These pathways lead to the binding of nuclear factor- κ B (NF- κ B) and activator protein-1 (AP-1) to the promoter regions of genes encoding proinflammatory cytokines, chemokines, inducible nitric oxide (NO) synthase (iNOS), and metalloproteinases.⁶³ Similarly, activation through TLR proteins proceeds via Myd88 and a chain of intracellular mediators (see Box 187.2) that also converge on NF- κ B. Other adaptor molecules in the TLR2 and TLR4 signaling pathways (e.g., CD14) may also play a role.

Although the inflammation that urate crystals trigger via the inflammasome is clearly detrimental in the context of acute gout, it may play a physiologic role in activating the innate immune response by providing a “danger” signal.³ Cell injury results in the release of urate, which accumulates in the microenvironment. Free urate or MSU crystals can then stimulate phagocytes and other resident cells. Danger signals from urate crystals and from other purines (e.g., ATP) may also help trigger the adaptive immune response by activating antigen-presenting DCs.³ DCs provide stimulatory signals that help drive the activation of T lymphocytes, including type 17 helper T-cell (Th17) differentiation.

Acute inflammatory mediators

Activation of cells by urate microcrystals leads to the production of a diverse array of mediators. The S100 protein heterodimer formed by the calgranulin proteins S100A8 and S100A9 (formerly “myeloid release proteins” MRP8 and MRP14) is among the earliest inflammatory mediators produced in response to urate crystals. S100A8/9 is one of the most abundant proteins in the neutrophil cytoplasm.

S100A8/9 is also elevated in synovial fluid and serum during acute gout and may be an important initial stimulus to attract and activate other cells.⁶⁴ Release of S100A8/9 involves the Src-family tyrosine kinase Syk and phosphatidylinositol-3'-kinase pathways and also appears to be dependent on the CD11b and Fc γ RIII (CD16) receptors.

IL-1, IL-6, chemokines (see the next section), granulocyte-macrophage colony-stimulating factor, and tumor necrosis factor- α (TNF- α) are among the mediators released starting within 30 minutes after exposure of cells to MSU crystals.

Another early response to cytokine release is increased expression of E-selectin on nearby vascular endothelial cells. A further mediator involved in experimental crystal-induced inflammation is endothelin-1, a peptide modulator of neutrophil migration produced by vascular endothelium.⁶⁵ These mediators contribute to massive neutrophil migration toward the MSU crystals that have triggered the episode.

Chemokines

Chemokines of the CXC family are important for attracting and activating neutrophils and are the major cytokines in acute gouty synovial fluid. Mice with a targeted disruption (“knockout”) of the gene for the chemokine receptor CXCR2 have a reduced neutrophil component in response to MSU crystals⁶⁶ (Fig. 187.10; also see Fig. 187.9 and Box 187.2). In addition,

Fig. 187.9 Crystals interact with cell-surface receptors and their associated signaling complexes and are phagocytosed by the cell. Rupture of the phagolysosome releases the crystals into the cytoplasm, which allows interaction with the inflammasome and leads to activation and release of interleukin-1 (IL-1). Signaling protein kinases and promoters for cytokines and other proinflammatory genes are activated, with the release of a diverse array of inflammatory mediators (see text). Urate and other crystals also interact with lipid membranes and bind to cytosolic and membrane-bound proteins, thereby acting directly at important steps controlling proinflammatory signaling.

CXCL-8, CXCL-1 (growth regulated α , [Gro- α]), CXCL-2 (macrophage inflammatory protein-2 α [MIP-2 α], Gro- β), and CXCL-3 (MIP-2 β , Gro- γ) have been implicated.

The chemokine CCL-2 (monocyte chemoattractant factor-1 [MCP-1]) aids in recruitment of monocytes to the sites of inflammation induced by urate crystals.⁶⁷ As with other mediators, assigning relative significance to individual chemokines is difficult—the chemokine family is large and there is substantial overlap between the various chemokines binding a given receptor, redundancy in the functions assigned to different chemokines and receptors, and incomplete translation between mediator actions *in vitro* and in animal models and their functions in human disease.

Other mediators

MSU crystals activate *de novo* synthesis of inducible cyclooxygenase-2 (COX-2) and phospholipase A₂ and produce the inflammatory prostanoids prostaglandin E₂ and thromboxane A₂ in phagocytes.^{62,68} Prostaglandin E₂ causes vasodilatation, edema, and further leukocyte immigration. The clinical efficacy of COX inhibition in treating acute gout confirms a significant role for prostanoids in urate crystal inflammation.

Urate crystals stimulate neutrophils to undergo the respiratory burst and produce reactive oxygen species, particularly O₂^{•-}.⁶⁹ Urate crystals also incite NO production.⁶³ NO synthesis by iNOS (NOS2) has been demonstrated in cells relevant to the inflammation of acute gout, including macrophages, fibroblasts, chondrocytes, and endothelia.

Release of NO involves signaling pathways similar to those of the proinflammatory cytokines. Depending on its concentration and microenvironment, NO can mediate regulatory or direct toxic effects and can influence neutrophil activation and apoptosis.

Neutrophil activation

Resident synovial cells and trafficking monocytes contribute to the initial burst of proinflammatory mediators important in the initiation of gouty arthritis. Much of the full-blown response observed clinically is mediated by neutrophils. Synovial fluid aspirated during attacks of acute gout reveals neutrophil counts in a range up to that seen in acute pyogenic septic arthritis.

Neutrophils initially attach to the synovial vascular endothelium through their selectin ligands. Stronger adhesion occurs when the vascular endothelia express integrin molecules in response to the chemokines and cytokines produced in adjacent tissues.

The neutrophils then exit the synovial capillaries and migrate through the synovial matrix to the joint cavity, aided by the chemotactic gradient. The proinflammatory cytokines prime the neutrophil for an amplified oxidative and degranulation response to crystals.

Neutrophils have a shorter half-life (hours) than any other circulating leukocyte. Unless they are activated, normal neutrophils soon die. Inflammatory mediators implicated in gout, particularly colony-stimulating factors, IL-1, IL-6, chemokines, and prostaglandins, prolong neutrophil survival by inhibiting spontaneous apoptosis.

Fig. 187.10 Urate crystals can stimulate a variety of cells to produce a diverse array of inflammatory mediators, depending on the coating of the crystal and the receptiveness of the cell. Many mediators have been implicated in experimental settings, but the dominant mediators in human gout are uncertain; the clinical response of acute gout to nonsteroidal antiinflammatory drugs/coxibs and to specific interleukin-1 (IL-1) antagonists supports key roles for prostanoids and for IL-1, respectively. CCL2: MCP-1, macrophage chemoattractant factor 1; CXCL8: IL-8; LTB₄, leukotriene B₄; N, nitrogen; O, oxygen; PGE₂, prostaglandin E₂; TNF- α , tumor necrosis factor- α .

Neutrophils and macrophages within synovial fluid avidly engulf urate crystals. Lysosomal enzymes then remove the protein coating that the crystal has acquired in the synovial membrane and cavity. In the uncoated state, MSU crystals have increased reactivity with proteins and membranes. Neutrophil activation is marked by activation of phospholipases and by inositol triphosphate production, which leads to cytoplasmic calcium flux. Urate crystals also induce leukotriene production.

Depending on crystal concentration and coating, MSU crystals can then lyse the phagolysosomal membrane and spill the phagocytosed crystals and toxic lysosomal contents (proteases, reactive oxygen species) into the neutrophil cytoplasm (see Fig. 187.9). Phagosome lysis allows the urate crystals to interact with the inflammasome but can also lead to death of the phagocyte; this releases the lysosomal contents together with newly synthesized acute inflammatory mediators.

According to the intensity of the response and the size and number of joints affected, cytokines, including S100A8/9, IL-1, IL-6, IL-8, MCP-1, and TNF- α , are produced in sufficient quantity to enter the circulation and stimulate an acute-phase response. Patients with acute gout are often systemically unwell, with fever and leukocytosis, and in some cases display a systemic inflammatory response syndrome easily confused with sepsis (see Chapter 188).

The clinical response of acute gout to COX-2 inhibitors and IL-1 antagonists suggests that prostanoids and IL-1 (see Chapter 189) are prominent mediators of the intense acute inflammation characteristic of acute gout.⁷⁰ Other pain mediators include kinins, neuropeptides such as substance P, and mast cell products.

Termination of the acute attack

Even without medical intervention, acute gout is almost always self-limited. The classic attack resolves spontaneously within a week or two. This is an intriguing paradox given the overlap between gout and other arthropathies at the level of the molecular mediators involved and the persistence of the crystals that initiated the attack.

The increase in vascular permeability once acute synovitis has begun allows increased entry of antiinflammatory crystal-coating macromolecules from plasma, such as apo-B. Increasing urate crystal coating with apo-B and locally produced apo-E and TGF- β can inhibit neutrophil activation.

Systemic antiinflammatory mediators include the melanocortins, products of the hypothalamic-pituitary axis, including adrenocorticotropin (ACTH) and melanocyte-stimulating hormone (MSH). ACTH stimulates the release of corticosteroids from the adrenal cortex. Melanocortins also have a direct antiinflammatory effect on macrophages in the inflamed joint via macrophage melanocortin receptors.⁷¹

A number of antiinflammatory mediators have been implicated in the resolution phase of an acute gout attack. These mediators include apo-E, TGF- β , IL-10, IL-1 receptor antagonist, soluble TNF receptors, intracellular cytokine inducible SH2-containing protein (CIS) and suppressor of cytokine signaling 3 (SOCS3),⁷² and inducers of the nuclear hormone receptor peroxisome proliferator-activated receptor (PPAR- γ)⁷³ (see Fig. 187.7).

Resolution of the acute attack may be aided by the presence of progressively more differentiated macrophages arising in response to the cytokine milieu,⁷⁴ although other studies suggest that mature macrophages are as capable as monocytes of initiating responses to urate crystals⁴⁹ and removing neutrophils through apoptosis and phagocytosis.

CHRONIC GOUTY ARTHRITIS

Other than the serum urate level, risk factors for recurrence during the intercritical phase have not been studied in detail but are likely to be similar to

those for the initial development of gout. Hyperuricemia, synovial membrane microtophi, and synovial fluid crystals persist in a large proportion of these patients. At a clinical level, some chronic gout patients have no overt synovitis, whereas others have ongoing but relatively low-grade inflammation.

Persistent nests of crystals are enveloped by a granuloma-like chronic inflammatory response, with a corona zone of differentiated macrophages and multinucleated giant cells surrounded in turn by a fibrous layer. Both adaptive and innate immune cells are present within the tophus, and proinflammatory cytokines, including IL-1 and TNF- α , are expressed within the corona zone (Fig. 187-11).⁷⁵

Erosion of bone occurs frequently in chronic gout, particularly in proximity to intraarticular or periarticular tophi, and generally has a radiographic appearance distinct from that seen with the erosions of rheumatoid arthritis. Patients with severe erosive and tophaceous gout have elevated circulating levels of receptor activator of NF- κ B ligand (RANKL) and macrophage colony-stimulating factor, factors that aid the maturation of bone-resorbing osteoclasts.⁷⁶ T cells present within the tophus express RANKL and may contribute to joint damage.⁷⁷

Urate crystals also have profound effects on osteoblasts and cause reduced cell viability, function, and differentiation.⁷⁸ In addition, these crystals reduce the expression of osteoprotegerin, a decoy receptor that inhibits osteoclastogenesis by preventing the binding of RANK to its ligand. High numbers of osteoclasts and infrequent osteoblasts are present at the bone-tophus interface in patients with chronic gout.^{76,78} Together, these data suggest that the bone erosion in gout is due to uncoupling of osteoclast and osteoblast function, which in turn promotes bone resorption at sites of urate crystal deposition.

Cartilage damage, characterized by radiographic joint space narrowing, is a relatively late manifestation of chronic gout. Histologic studies have shown that urate crystals are deposited radially in the superficial layers of articular cartilage, and cartilage surfaces in chronic gout are often described as being diffusely “dusted” with white crystal deposits.⁷⁹ Ultrasound studies have highlighted the close relationship between urate crystals and articular cartilage. The “double-contour” ultrasound sign can be visualized over the superficial margin of the articular cartilage in gouty joints and is thought to represent urate crystal deposition.⁸⁰

Urate crystals interact with chondrocytes to promote degradation of the cartilage matrix by inducing NO generation and expression of matrix metalloproteinase-3 (MMP-3) in articular chondrocytes through TLR2 signaling and upregulation of NF- κ B.⁸¹ Increased expression of other MMPs has also been observed in synovial fibroblasts stimulated with urate crystals⁸² and in macrophages obtained from gouty synovial tissue and within the tophus.⁸³

Findings on magnetic resonance imaging and ultrasound suggest that a high proportion of patients with gout and normal plain radiographs have occult joint damage.⁸⁴ Joints with persistent crystals may be subject to ongoing progressive damage even in the absence of acute flares.

Fig. 187.11 The central mass of monosodium urate crystals is surrounded by a corona of cells, including mature macrophages and multinucleated giant cells. Cells of the adaptive immune response are also present: T and B lymphocytes and plasma cells. (Adapted with permission from Dalbeth N, Pool B, Gamble GD, et al. Cellular characterization of the gouty tophus: a quantitative analysis. *Arthritis Rheum* 2010;62:1549-56.)

MODELS OF GOUT

Hyperuricemia models

No naturally occurring mammalian models for gout are available because most nonprimate mammalian species have uricase activity and maintain much lower urate levels than humans, and uricase-lacking nonhuman primates are vegetarians. Rodents, the most used source of animal models of arthritis, do not suffer spontaneous gout. Urate balance has been manipulated in several rodent models.

Mice with a homozygous urate oxidase gene knockout have severe hyperuricemia. Half die before 4 weeks of age as a result of renal failure and nephrogenic diabetes insipidus caused by uric acid crystal deposition within the kidneys.⁸⁵ Gout does not develop in surviving animals. Mice deficient in HPRT (the enzyme defect underlying Lesch-Nyhan and Kelley-Seegmiller syndromes in humans) or in both HPRT and adenine phosphoribosyltransferase (APRT) have normal urate excretion rates and no overt behavioral changes.⁸⁶

Oxonic acid, an inhibitor of urate oxidase, has been used to study the direct effects of urate on the vasculature. Treating rats with oxonate produces elevations in plasma urate levels that are modest by human standards and not associated with overt tissue deposition of urate crystals or with gout-like inflammation.

Urate crystal injection models

Injection of MSU crystals allows the study of crystal-induced inflammation under controlled circumstances. Urate crystals have been injected locally into several species, including rodents, rabbits, pigs, guinea pigs, dogs, and humans. They provoke a transient dose-dependent acute inflammatory response. Injection routes include intradermal, subcutaneous, palatal, intra-peritoneal, intraarticular, and into subcutaneous pouches produced by repeated injection of air.

An example of the use of urate crystals to study human inflammation is shown in Figure 187.12. Inflammation becomes clinically apparent within 2 to 4 hours of intradermal injection, peaks at 8 to 24 hours, and then subsides spontaneously with no significant sequelae. This and similar models provide safe and reasonably quantifiable systems to study aspects of cell trafficking, inflammatory regulation, mediator release, and pharmacologic inhibitors *in vivo*.

Although crystal injection models have allowed exploration of certain aspects of the inflammatory response, there are important caveats. In addition to the generally poor track record of extrapolating between induced preclinical models and spontaneous human arthritis, synthetic crystal preparations cannot easily mimic the protein, apolipoprotein, and lipid coatings acquired when urate crystals form *in vivo*. Injection into sites other than joints means an initial encounter with responding cells that are unlike those in the synovium.

Fig. 187.12 Crystal-induced experimental inflammation: example of a model system for studying inflammatory events triggered by monosodium urate crystals in human volunteers. (a) Erythema visible 8 hours after the intradermal injection of graded doses of crystals (from left: 2.5, 1.25, 0.63, 0.32, 0.16 mg, and saline control). (b) Measurement of increased skin blood flow in this subject via laser Doppler flux. Urate crystals have been injected into skin and other accessible sites in humans and experimental animals to provide models of acute inflammation driven by cytokines (particularly interleukin-1 [IL-1], IL-6, and tumor necrosis factor- α [TNF- α]), chemokines (particularly IL-8), and prostanooids.

Most experimental animal species possess uricase. This limits the development of a model of chronic gouty arthropathy to further examine the mechanisms of bone and joint disease in chronic gout.

THE GENETICS OF GOUT

A familial diathesis to gout was first noted by Seneca 2 millennia ago. A positive family history has been reported in as few as 10% and as many as 80% of gout patients. This range reflects differences in the populations studied, the definitions used, and the vigor applied to ascertainment. Genetic influences on hyperuricemia and gout are, in most instances, multigenic.

Environmental factors are often required to exacerbate an underlying predisposition. For example, gout in Tokelau Islanders increased ninefold after migrating to New Zealand and adopting aspects of a Western industrialized lifestyle.⁸⁷ Assessing the relative contributions of genes and environment is difficult because certain pertinent “nongenetic” factors have a strongly heritable component, including dietary preferences and alcohol intake, and environmental exposures may be needed to “unmask” certain genetic influences. Contemporary estimates of the heritability of serum uric acid levels have ranged from 40% to 63%.⁸⁸

Genes that influence gout could in principle act at any one of several checkpoints on the path to crystal-induced inflammation. For example, they could affect urate production, renal handling of urate, crystal nucleation and enlargement, the crystal coating, or the cellular and soluble mediator components of the acute response when cell meets crystal or the amplification of this response. In support of the importance of genes influencing urate excretion, monozygotic twins show a tighter concordance than dizygotic twins for fractional renal uric acid clearance.⁸⁹ Genome-wide association studies (GWASs) indicate roles for genes involved in urate production, urate excretion, and control of inflammation.⁹⁰

Large, well-powered GWASs have revealed associations of many other genes encoding renal urate transporters (including *ABCG2*, *SLC2A12*, *SLC16A9*, *SLC17A1*, *SLC17A3*, and *SLC22A11*) with serum urate concentrations and gout.^{30,90} *SLC2A9* has the strongest effect on serum urate levels. Genetic associations between the serum urate level and the *PDZK1* gene³⁰ further support the importance of the URAT1-PDZ-NPT complex in controlling net urate reabsorption and secretion.

Consistent with a significant role in urate excretion, homozygosity for a loss-of-function mutation in *URAT1/SLC22A12*, the gene for the renal urate anion exchanger (see earlier), is the most common cause of renal hypouricemia (Online Mendelian Inheritance in Man [OMIM] 607096, 220150) in Japanese patients.²⁵ This polymorphism is more common in healthy Japanese than in gout patients, thus suggesting that it provides protection against gout.⁹¹

SLC2A9 has a stronger effect in women than in men and *ABCG2* a stronger effect in men.^{30,92} The promoter regions for some of the urate transporter genes contain hormone-responsive elements, which may underlie these effects.

Metabolic genes

Several well-defined purine metabolic enzyme defects lead to overproduction of urate (see Table 187.2), but they are uncommon. Other metabolic genes have effects that are less direct and less dramatic. There is an association between the serum urate level and *GCKR*, which encodes glucokinase regulatory protein, a regulator of glucokinase.⁹³ Glucokinase is an important enzyme in the glycolytic pathway and acts as a glucose sensor. *GKCR* has in turn been linked with metabolic traits associated with gout, including insulin resistance and hyperlipidemia. Other implicated genes are involved in sugar metabolism and in the production of purine precursors through the pentose phosphate pathway.⁹⁰

Genes influencing crystal formation and crystal-triggered inflammation

Gout does not develop in many hyperuricemic people. Moreover, the genes currently known to influence urate levels account for just a small proportion of the heritability of gout (less than 10% when stringent criteria are applied). This suggests that diverse mutations or a combination of many individually “weak” genes contribute to the genetic predisposition to gout. Despite powerful contemporary epidemiologic and genetic techniques, the relative contributions of genes versus environment (“nature vs. nurture”) remain uncertain.

Numerous polymorphisms have been identified in the promoter and structural regions of the genes for inflammatory cytokines, cytokine

receptors, and cellular signaling molecules, including NLRP3 and members of the IL-1 family. Expression of one or more of these genes might modulate the inflammatory response to urate crystals. GWASs have also implicated several genes involved in the regulation of inflammation.⁹⁰ Associations between gout and cytokine gene polymorphisms have not been explored as robustly as, for example, the *URAT1* and *SLC2A9* associations.

Clinical gout

■ N. LAWRENCE EDWARDS

- Gout has an abrupt initial onset involving, most commonly, the big toe, ankle, or other joints of the foot.
- Upper limbs, especially the distal interphalangeal joint, are affected in chronic tophaceous or recurrent acute gout.
- Men in middle life who are obese and drink alcohol regularly are the most susceptible.
- Women, when affected, are most commonly taking diuretics or postmenopausal.
- Hypertension, hypertriglyceridemia, insulin resistance, and mild renal impairment can be associated.
- Hypoxanthine-guanine phosphoribosyltransferase deficiency, phosphoribosylpyrophosphate synthetase overactivity, or hereditary renal disease should be suspected in children, adolescents, or young adults with gout.

INTRODUCTION

Gout is by far the most common inflammatory arthritis that affects humans. Despite this, there are many widely held misconceptions about the disease, its causes, and its treatments. From a clinical perspective, gout is frequently perceived as a painful intermittent nuisance rather than the progressive, and ultimately destructive, form of arthritis that it is.

The gouty process actually begins years or decades before the patient develops any gout symptoms. When gout is viewed in this way, it becomes clear how, if it is left untreated, the process of urate accumulation over time will lead to greater destruction and will make treatment more difficult.

CLINICAL STAGES OF GOUT

Gout is a clinical disease associated with hyperuricemia and caused by the deposition of monosodium urate crystals in and around the tissues of joints. Gout is frequently epitomized by an acutely painful and swollen toe or foot. This is, however, only a single stage in the progression of urate deposition disease in the soft tissues and joints. Typical gout progresses from a usually prolonged initial period of asymptomatic accumulation of monosodium urate crystals in and around joints to a phase of acutely painful but self-limited episodes of monoarthritis or oligoarthritis to a final phase of chronically painful, deforming, and debilitating polyarthritis associated with the visible presence of soft tissue monosodium urate crystal deposits known as *tophi* (Fig. 188.1). Although it is traditional to think of the natural progression of gout in these three stages, it is more correct to view gout as a steady accumulation of monosodium urate crystals in and around joints from the earliest onset of hyperuricemia. Gout is a disease of urate burden.

The duration of each stage of gout can vary greatly from one person to another depending on numerous endogenous and exogenous factors. The most important of these factors is the degree of hyperuricemia.

Asymptomatic hyperuricemia

Definition

Hyperuricemia is a common biochemical abnormality that has become much more common over the past 40 years. In extracellular fluids, 98% of uric acid is in the form of the urate ion at pH 7.4. Hence it is conventional

to refer to the serum and synovial fluid forms as *urate* but the urinary form as *uric acid*. The physiologic definition of hyperuricemia is a concentration of serum urate above 6.8 mg/dL (402 μ mol/L) because this level defines the saturation point of the sodium urate salt in biologic fluids at physiologic pH and temperature.¹ Inappropriately, commercial medical laboratories define the “normal” range of serum urate based on the population mean and its 95% confidence intervals. This definition of hyperuricemia clearly has no bearing on the pathologic potential of uric acid.

Demographic risk factors

The prevalence of hyperuricemia varies from country to country, but worldwide the percentage of adults with hyperuricemia has been increasing over the past four decades. In the United States, the Framingham study found the prevalence of serum urate levels higher than 7.0 mg/dL to be 4.8% in adults in the early 1970s, whereas the National Health and Nutrition Examination Survey (NHANES) for 2007-2008 reported hyperuricemia in 21% of both men and women.²

Many factors contribute to this observed rise in serum urate levels around the world, and the importance of individual factors can vary among countries and populations. Age is by far the most important risk factor in explaining the increased number of cases of hyperuricemia and gout. Men usually attain their adult serum urate levels shortly after puberty and maintain this level throughout life with modification only by diet, disease, and medications. When the percentage of the population over the age of 65 increases, as it has done in most industrialized nations, then the prevalence of hyperuricemia also increases. The effect of longevity on the prevalence of hyperuricemia is even more profound in women.³ Women's serum urate levels remain relatively low throughout most of their adult lives because of the uricosuric effect of estrogens. After menopause, the gap between male and female urate levels narrows, and a far higher percentage of elderly women than of young adult women have hyperuricemia and gout.

Kidney disease

The rising frequency of solid organ transplantation and the survival of patients with severe chronic kidney disease also contribute to the higher prevalence of hyperuricemia. The calcineurin inhibitors cyclosporine and tacrolimus have potent effects on serum urate levels by preventing uric acid secretion by transporters in the proximal convoluted tubules of the kidney and by diminishing glomerular filtration.^{4,5} In one study of renal transplant patients taking prednisone and either cyclosporine or azathioprine, the prevalence of hyperuricemia was 84% in those taking cyclosporine, whereas it was 30% in those taking azathioprine.⁶ Patients with advanced kidney disease have a high likelihood of being hyperuricemic even if they do not undergo renal transplantation. The survival of these patients has greatly improved over the past 4 decades, and therefore the contribution of kidney failure to the rising prevalence of hyperuricemia over the same period of time is substantial.

Influence of diet

Dietary trends have also been part of this epidemic of hyperuricemia. Western countries consume more meat and seafood, less dairy products, more sugar-sweetened beverages, and a higher proportion of beer compared with other alcoholic beverages than in decades past. All of these dietary changes promote higher uric acid levels.^{7,8} Serum urate levels have been shown to independently predict the development of hypertension⁹ as well as cardiovascular disease, cardiac failure, stroke, and kidney disease.^{10,11} Thus this period of asymptomatic hyperuricemia may not be the quiescent and benign initial phase of clinical gout that it was once considered to be. Similarly, the requisite changes in the joints and soft tissues of hyperuricemic patients that will ultimately go on to develop gout are taking place

THE STAGES OF GOUT

Fig. 188.1 A period of asymptomatic hyperuricemia is an obligatory precursor to clinical gout. The duration of this initial phase varies directly with the degree of serum urate elevation. A period of acute intermittent gout, lasting a decade or longer, is characterized by acute flares separated by asymptomatic intervals. If the disease is not treated, the majority of individuals progress to a chronic debilitating arthritis with clinically apparent soft tissue tophi—collectively referred to as *advanced gout*. Underlying the clinical manifestations of gout, the clinical course of untreated gout is one of gradual accumulation of urate stores throughout the body (shaded area).

during this time of asymptomatic hyperuricemia. The supersaturation of urate in synovial fluid leads to crystallization of monosodium urate, and these crystals gradually form small microtophi on the cartilage surface and in the synovium years to decades before the first clinical attack of gout. The presence of these preexisting microtophi has been demonstrated directly by arthroscopy¹² and indirectly by ultrasonography and magnetic resonance imaging.^{13,14}

Other risk factors

Obesity is another major risk factor related to the increasing prevalence of hyperuricemia and gout. In fact, the obesity epidemic in most Western countries is closely paralleled by the increased prevalence of hyperuricemia and gout.¹⁵ Uric acid levels are raised in the setting of obesity because of both diminished renal elimination of uric acid and increased production of uric acid in the body.¹⁶

A number of medications in common use also contribute to the higher prevalence of hyperuricemia. Low-dose aspirin and diuretics are widely used by adults who have hypertension or are at risk of cardiovascular disease. Aspirin dosages as low as 75 mg/day have been shown to have an impact on serum urate levels¹⁷ and are taken by more than half of all persons at high risk of cardiovascular events.¹⁸ Similarly, thiazide diuretics alone or in combination with other antihypertensives are among the most commonly prescribed of all medications.

Hyperuricemia and onset of gout

Although the initial stage of gout, asymptomatic hyperuricemia, goes unrecognized clinically in the vast majority of gout patients, it is an important period in altering structural anatomy and fostering the development of the comorbid medical conditions associated with gout. The period of asymptomatic hyperuricemia typically lasts for several decades but may be considerably shorter in patients with marked elevations of serum urate levels. This is especially true in patients with certain inborn metabolic errors and in patients taking cyclosporine, in whom the period of hyperuricemia preceding clinical gout may be as short as several years.¹⁹ Not everyone with hyperuricemia eventually has gout. In the Framingham study, gout developed in only 12% of patients with urate levels between 7.0 and 7.9 mg/dL over a 14-year period.²⁰ Patients with urate levels higher than 9.0 mg/dL had a sixfold greater likelihood of progressing to clinical gout.

Acute intermittent gout

The initial attack of acute gout usually occurs in men between the fourth and sixth decades of life. In women, the age at onset is later and varies with

BOX 188.1 KEY COMPONENTS OF GOUT FLARES

- Marked tenderness and swelling of affected joint
- Acute onset with maximum pain in 4 to 12 hours
- Recurrent pattern of similar attacks
- Marked impairment of physical function
- Resolution of symptoms within 3 to 14 days

Fig. 188.2 Podagra or acute gout of the first metatarsophalangeal joint is shown. The hyperintense erythema with a dusky hue is characteristic. The area of inflammation usually extends beyond the region of the involved joint.

several factors, the most important of which is the age of menopause. The typical gouty attack is usually heralded by the rapid development of warmth, swelling, erythema, and exquisite pain in the affected joint. These symptoms can appear at any time of the day, but there is a slightly higher incidence of onset during the sleeping hours.²¹ Pain escalates from faint twinges to its most intense level over a short 4- to 12-hour period. The initial attacks are usually monoarticular, and in approximately half of the cases the arthritis involves the first metatarsophalangeal joint. Eventually this joint is affected in 90% of individuals with gout. Other joints that are frequently affected in the early phase of acute intermittent gout are the midfoot, ankle, heel, and knees. After the first five to eight episodes of acute gout, other joints, including the fingers, wrists, and elbows, can also be affected. Classically, patients cannot stand even the lightest of touches or bed sheets on the affected joint, and most patients find walking difficult or impossible when lower extremity joints are involved.

A recent study attempted to provide criteria for defining a gout flare from the perspective of gout experts and patients alike.²² In general, the description clusters of classic joint inflammation, the marked severity of joint symptoms, and the stereotypical nature of the onset and resolution of an acute attack were found to be the most meaningful clinical clues that can help distinguish a gout flare from other forms of acute monoarthritis (Box 188.1).

The initial flares of gout occur with explosive suddenness, and within 4 to 12 hours the gouty individual is not capable of walking. In an acute attack the skin over the affected joint soon becomes reddened and warm with extreme tenderness to touch or movement of the joint (Fig. 188.2). As suggested over a 100 years ago by Sir William Osler, a distinguishing characteristic differentiating an acute gouty joint from a septic joint is the appearance of the overlying skin: a gouty joint has shiny, tense skin with a cyanotic or mauve hue, whereas a fiery red color is more characteristic of a septic joint. Although this difference has not been subjected to a formal investigation, it is widely accepted. Systemic symptoms such as

fevers, chills, and malaise may also accompany acute gout and may lead to some confusion when trying to distinguish acute gout from a septic joint.

The previous clinical description refers to the classic presentation of acute gout. There are other forms. McCarty^{22a} described a much milder variation with trivial episodes of pain (“petite attacks”) lasting only minutes to hours and sometimes recurrent over several years before the first dramatic gouty attack. Another atypical presentation of acute gout occurs more often in elderly women. In these women, the initial flares are in the upper extremity joints and may involve several joints. Early onset of upper extremity involvement and the occurrence of oligoarticular or polyarticular flares are seen more commonly in women than in men.²³

Factors precipitating flares

Factors capable of provoking an acute flare include anything that can alter the usual stable microenvironment surrounding the microtophi in the joint space. The physical factors that are most commonly altered to provoke an attack are the pH of the surrounding synovial fluid and the concentration of urate. Destabilization of the microtophi leads to shedding of crystals into the joint space and initiation of the acute attack. Trauma to the joint with or without intraarticular bleeding or systemic acidosis associated with surgery can both change the intraarticular pH enough to foster a flare. Similarly, any condition or medication that dramatically raises or lowers urate levels in the synovial fluid will also destabilize the microtophi, resulting in “mobilization flares.” Dietary exposures such as abnormally high intake of meat, seafood (especially shellfish), and alcohol (especially beer) raise urate levels and cause crystal shedding. Crystal shedding can also be induced by factors that rapidly reduce serum urate levels, such as allopurinol. Interestingly, factors that cause sudden lowering of serum urate levels are more likely to trigger attacks than those that raise urate levels.

Natural history of acute attack

One of the hallmarks of the acute gout flare is its self-limited nature. In fact, a clear and detailed history of an acute arthritic attack followed by a completely asymptomatic intercritical period before a recurrence of a similar attack is valuable in pointing toward a clinical diagnosis of gout. The initial attacks themselves last between 5 and 10 days. The intercritical period separating early attacks may last several months or up to several years, with a mean duration of 11 months. As the disease progresses in the untreated patient, acute attacks occur with increasing frequency and are often oligoarticular or polyarticular, more severe, and longer lasting (see Fig. 188.1). The corollary to this pattern of flares is that the length of the intercritical period becomes progressively shorter. Even when the acute gouty flare has completely subsided, monosodium urate crystals remain in the synovial fluid,²⁴ and low-grade inflammation persists within the joint, as evidenced by white blood cell counts in the range of 1000 to 2000/mm³. Thus the entire stage of acute intermittent gout is one of persistent low-grade inflammation with relatively short periods of acute severe inflammation. This stage usually persists for 10 years or longer before progression to the chronically symptomatic stage of advanced gout. However, depending on the cause and degree of hyperuricemia, the acute intermittent stage of gout may last for as short as 3 to 4 years or for longer than 20 years.

Advanced gouty arthritis

The transition from acute intermittent gout to advanced gout occurs when the intercritical period between flares is no longer associated with freedom from pain (see Fig. 188.1). This stage was previously called *chronic tophaceous gout*; however, although the subcutaneous tophus is the most characteristic lesion of advanced gouty arthritis, it is not always present. In addition, patients have been reported who have tophi as their initial clinical manifestation.²⁵ In this stage of gout, the involved joints are persistently uncomfortable and swollen, although the intensity of these symptoms is much less than during the acute flares. Flares can continue to occur against this painful background, and without therapy they will recur as often as every few weeks. The level of background pain may also steadily increase with time if appropriate therapies are not instituted. Macrotophi or clinically evident tophi may or may not be detected on physical examination in the early phases of advanced gout, but bony or periarticular tophi are almost always detected by ultrasonography or magnetic resonance imaging.¹⁴ Polyarticular involvement becomes much more frequent at this time. With diffuse and symmetric involvement of small joints in the hands and feet, advanced gout can occasionally be confused with the symmetric polyarthritis of rheumatoid arthritis (Fig. 188.3). The severity of and disability associated with the erosions and bony destruction of advanced gouty arthritis are similar to those observed with rheumatoid arthritis.²⁶

Fig. 188.3 Advanced gout of the hands and wrists demonstrates an asymmetric arthritis with articular and interarticular tophi. The large tophus involving the distal left fourth digit shows very superficial crystalline deposits.

Role of subcutaneous tophi

A subcutaneous tophus is a well-organized collection of monosodium urate crystals and is pathognomonic for gout, as is the destructive arthritis of advanced gout. Tophi can lead to pain and dysfunction in their own right. Similar-appearing nodules are clinically observed in other rheumatic disorders such as rheumatoid arthritis and multicentric reticulohistiocytosis, which may lead to diagnostic confusion. Besides their appearance, there are other parallels between gouty tophi and rheumatoid nodules. The nodular aspects of both diseases are generally observed in the most chronic and severe cases but are not a universal consequence of the disease process. The presence of both types of nodules is also closely correlated with high titers of their respective serologic markers: serum urate in the case of gout and rheumatoid factor in the case of rheumatoid arthritis.

Subcutaneous gouty tophi may be found anywhere in the body but occur most commonly in the fingers, wrists, ears (Fig. 188.4), knees, olecranon bursae, and pressure points such as the ulnar aspect of the forearm and the Achilles tendon. In patients with coexisting nodal osteoarthritis, tophi have a propensity for forming in Heberden nodes (Fig. 188.5). Tophi may also occur in connective tissues at other sites such as the renal pyramids, heart valves, and sclerae.²⁷

Before the advent of urate-lowering therapies in the 1950s and 1960s, as many as 50% of patients with gout eventually developed clinical evidence of tophi.²⁸ With the introduction of allopurinol and probenecid, the incidence of tophaceous gout has declined.

Nonclassic gout

The descriptions of the three stages of classic gout in the previous section are most relevant to the typical middle-aged man who is obese and has one or more of the comorbid medical conditions associated with gout, such as hypertension, cardiovascular disease, renal insufficiency, or dyslipidemia. There are other presentations of gout that do not fit this profile and whose manifestations are atypical enough that the clinician may miss the diagnosis.

Early-onset gout

Approximately 5% of all patients with gout experience the onset of their symptoms before the age of 25. These patients with early-onset gout are a special subset who usually do not have obesity or the comorbidities of gout, experience a more accelerated clinical course, generally have a strong family history of gout, and require more aggressive antihyperuricemic therapy than do typical individuals with gout. In large epidemiologic studies, a family history of gout and/or nephrolithiasis is present in 25% to 30% of patients with classic gout. In early-onset gout, a family history is found in about 80%. In this younger group, detailed questioning about the patient's family history over several generations may yield enough information to suggest a

Fig. 188.4 Subcutaneous tophi along the helix of the ear are uncommon but are ready sources of monosodium urate crystals for microscopic confirmation of gout.

Fig. 188.5 Large tophi involving the distal interphalangeal joints are commonly seen in gouty patients with preexisting Heberden nodes. This is particularly characteristic of late-onset gout.

mode of inheritance (X-linked or autosomal dominant or recessive). The measurement of 24-hour urine uric acid excretion and calculation of the urate clearance is also very helpful in classifying these patients with early-onset gout into the subgroups of uric acid overproducers and those with diminished fractional uric acid excretion (uric acid underexcretors).

Specific genetic deficiencies

Diseases associated with urate overproduction in children and young adults include enzymatic defects in the purine pathway, glycogen storage diseases, some genetic errors of urate transport in the kidney, as well as hematologic disorders such as hemoglobinopathies and leukemias.

The two inborn errors of purine metabolism that are associated with urate overproduction are both X-linked and both have severe phenotypes in which the very early onset of gout and kidney stones is combined with neurobehavioral and neurodevelopmental impairments. Both enzymatic abnormalities also have milder phenotypes with slightly later onset of gout and nephrolithiasis and milder or no neurologic impairments.

- A complete deficiency of hypoxanthine-guanine phosphoribosyltransferase (HPRT) is an inherited X-linked condition with the characteristic presentation known as *Lesch-Nyhan syndrome*.²⁹ These boys develop gout and kidney stones in the first decade of life if not treated very early. They also develop severe neurologic manifestations in infancy or early childhood consisting of variable mental retardation, dystonia, and compulsive self-mutilating behavior. A milder phenotype is found in boys with a partial deficiency of the HPRT enzyme. This usually manifests as the development of gout and/or kidney stones in male teenagers who are free of neurologic abnormalities. This X-linked partial deficiency of HPRT is referred to as *Kelley-Seegmiller syndrome*.³⁰
- The other purine enzyme abnormality associated with early-onset gout is phosphoribosylpyrophosphate (PRPP) synthetase overactivity. One of the two phenotypes of this X-linked disease is the infantile-onset form in which gout and uric acid nephrolithiasis are combined with neurodevelopmental impairment, including sensorineural hearing loss. It is caused by a point mutation in the PRPP synthetase gene that makes it insensitive to allosteric downregulation by purine nucleotides. The milder phenotype of this enzyme overactivity can be seen in older children, who have gout, kidney stones, and either mild or no neurologic impairment. This form of PRPP synthetase overactivity is caused by overexpression of a normal (nonmutated) PRPP synthetase gene.³¹

Glycogen storage disease (GSD) types I, III, V, and VII are associated with early-onset gout and are inherited as autosomal recessive diseases.^{32,33} In the hepatic form of von Gierke disease (GSD type IA) or glucose-6-phosphatase deficiency, childhood hyperuricemia can lead to acute and chronic gout in the adolescent years. The other components of this phenotype include short stature, hepatomegaly, hypertriglyceridemia, and fasting hypoglycemia. The reason for hyperuricemia in these children is an accelerated degradation of adenosine triphosphate in the liver. In the other forms of GSD the hyperuricemia is a less consistent finding, and documented cases of childhood or adolescent gout are much rarer. Type III disease, or Cori or Forbes disease, has a clinical picture very similar to that of type I disease except that serum urate and lactate levels are generally normal in the very young and in nonexercising older children. The glycogen debrancher enzyme is deficient in GSD type III. GSD type V (McArdle disease) and the very rare GSD type VII (Tarui disease) are enzymatic deficiencies in which the primary disturbance in glycogen homeostasis occurs in skeletal muscle. In McArdle disease, the deficient enzyme is muscle glycogen phosphorylase; the disorder manifests as exercise-induced cramps and can lead to rhabdomyolysis and renal failure. Accelerated adenosine triphosphate breakdown and enhanced lactic acid formation can lead to hyperuricemia and gout. Tarui disease, on the other hand, is caused by phosphofructokinase deficiency, which leads to enhanced purine nucleotide formation and turnover.

Childhood kidney disease

Although any form of childhood kidney disease that results in reduced glomerular filtration rate can cause hyperuricemia, there are only two diseases that consistently lead to gout in individuals in their teens and 20s. Familial juvenile hyperuricemic nephropathy (FJHN) is a rare autosomal dominant trait that inevitably causes childhood hyperuricemia, frequently resulting in gout in postpubertal adolescents.³⁴ The functional reason for hyperuricemia in children with FJHN is that the fractional excretion of urate by their kidneys is only half that seen in normal kidneys. In time, this deficiency leads to end-stage renal disease, usually by midlife. Autosomal dominant medullary cystic kidney disease (MCKD) is another inherited nephropathy that frequently results in gout. The gout associated with MCKD typically occurs in the third and fourth decades of life—much later than in FJHN. Multigenerational linkage analysis of MCKD shows at least two genetic abnormalities: one on chromosome 1 and the other on chromosome 16. Interestingly, the abnormal genetic locus on chromosome 16 found in some patients with MCKD is the same locus associated with FJHN. The chromosome 16p12 locus that contains the candidate intervals for FJHN and MCKD type II represents six genes, including the uromodulin gene (*UMOD*). The precise mechanism by which the uromodulin gene and its product, the Tamm-Horsfall protein, causes hyperuricemia remains unclear.

Female gout

Gout is considered a disease of men, and in most epidemiologic studies women have represented only 5% of the total gout population.³⁵ There has been a doubling of the incidence of gout in women over the past 20 years, however, with the incidence in postmenopausal women equaling that of similarly aged men.³⁶ Premenopausal levels of estrogen promote an increased fractional excretion of uric acid by the kidneys. Natural and surgical menopause are associated with increased uric acid levels, and the use of estrogen replacement therapy in postmenopausal women is associated with decreased uric acid levels.³⁷

The comparative clinical features in male and female gout patients have been examined in four small studies.³⁸ All agree that women develop gout at a later age (approximately 7 years later than men) and have more comorbidities, especially hypertension and renal insufficiency.³ Two of the studies found that women were more likely to have advanced disease at the time of presentation, as manifested by more tophi and polyarticular disease and a greater frequency of upper extremity gout involvement. Several associated characteristics are seen almost twice as frequently in female gout patients than in their male counterparts. These include diuretic use (95%), hypertension (73%), renal insufficiency (50%), and preexisting osteoarthritis (38%). The relationship to nodal osteoarthritis of the hands is interesting because there have been many clinical reports of patients in whom the initial presentation of postmenopausal gout occurred as a tophus developing in a preexisting Heberden node or Bouchard node (see Fig. 188.5).³⁸ In the rare case of gout in a premenopausal woman who is not taking a diuretic and does not have renal failure, the patient should be evaluated for the autosomally inherited causes of early-onset gout discussed in the preceding section.

Transplantation gout

Solid organ transplantation is a field of medicine that has blossomed in the 25 years since the introduction of the calcineurin inhibitor cyclosporine as an antirejection medication. Heart, kidney, and liver transplantations have improved and saved many lives, but the drug cyclosporine and its newer relative tacrolimus have also created many problems. Both drugs can cause renal dysfunction and hypertension and can dramatically reduce the kidney's ability to excrete uric acid.³⁹ Hyperuricemia develops in 75% to 80% of heart transplant recipients who routinely take cyclosporine to prevent allograft rejection.⁴⁰ The clinical course of gout associated with organ transplantation is markedly accelerated compared with the classic progression of primary gout. The stage of asymptomatic hyperuricemia lasts for 20 to 30 years in classic gout but is present for only 6 months to 4 years in cyclosporine-induced disease. Similarly, the duration of the acute intermittent gout stage is only 1 to 4 years in transplant recipients, whereas it may last 8 to 15 years in classic gout.⁴¹

Saturnine gout

Hyperuricemia and gout are well-recognized complications of chronic lead intoxication. The mechanism of lead-induced hyperuricemia is poorly understood but does appear to involve diminished uric acid excretion by the renal tubule. This form of secondary gout caused by excessive lead ingestion is referred to as *saturnine gout*. The term *saturnine* is derived from the word *saturnus*, the ancient alchemist's name for lead, which was considered to be very cold like the planet Saturn.⁴²

COMORBID DISEASES ASSOCIATED WITH HYPERURICEMIA AND GOUT

For more than a century, gout has been associated with hypertension, diabetes, obesity, cardiovascular disease, and kidney disease. In fact, the

prevalence of gout and the prevalence of these comorbid conditions have risen in parallel over the past 100 years, and they have spread from one culture to the next in a linked fashion. More recently, the dyslipidemia, obesity, and insulin resistance that make up metabolic syndrome have been directly tied to both hyperuricemia and gout.

Hypertension

Studies from the 1950s and 1960s established a close link between hypertension and both hyperuricemia and gout. There have been seven large epidemiologic studies since 2003 that have demonstrated serum urate level to be a consistent predictor of the later development of hypertension.⁴³ The Normative Aging Study showed that serum urate concentration independently predicted the development of hypertension when age-adjusted and multivariate models were used that included body mass, abdominal girth, alcohol use, serum lipid levels, plasma glucose level, and smoking status.⁴⁴ In fact, the preponderance of recent epidemiologic studies looking at the link between hypertension and hyperuricemia have concluded that a high uric acid level is an independent risk factor for the development of hypertension.

Kidney disease

Aside from the musculoskeletal system, the deleterious effect of hyperuricemia is most often manifested in the kidneys. Significant impairment of renal function was reported in up to 40% of patients with gout in studies conducted before the advent of effective urate-lowering therapies. Two large prospective studies in Japan looked at the relationship between baseline serum urate level and the eventual development of end-stage renal disease (ESRD)³⁵ or renal failure. The calculated incidence of ESRD per thousand persons was 1.2 for men without hyperuricemia and 4.6 for men with hyperuricemia. The effect was even more dramatic in women: the adjusted hazard ratio for developing ESRD due to hyperuricemia was 2.0 in men and 5.8 in women.⁴⁵

Cardiovascular disease

Hyperuricemia and gout are recognized as a significant risk factor for atherosclerotic disease in general and for coronary artery disease in particular.⁴⁶ NHANES-III showed that a serum urate level in excess of 6 mg/dL was an independent risk factor for coronary artery disease and that a serum urate level above 7 mg/dL was an independent risk factor for stroke.⁴⁷ Multiple studies have now confirmed this relationship between hyperuricemia, gout, and cardiovascular disease, although a direct causal mechanism has yet to be determined.

Metabolic syndrome

Hyperuricemia and gout are highly correlated with body mass index for both men and women. Metabolic syndrome is a constellation of disorders characterized by insulin-resistant hyperglycemia, hypertension, hypertriglyceridemia, and obesity. Although 20% to 25% of the adult population in the United States has metabolic syndrome, one study showed that 86% of gout patients met the criteria for metabolic syndrome.⁴⁸ In another recent study, nonobese individuals who developed metabolic syndrome were 10 times more likely to be hyperuricemic than a body mass index-matched cohort without metabolic syndrome.⁴³

Management of gout and hyperuricemia

■ ROBERT TERKELTAUB

- Therapeutic strategies for gout and hyperuricemia were subjected to a systematic and formal consensus review process and recently disseminated in the 2012 American College of Rheumatology guidelines.^{1,2}
- Management strategies involve distinct but linked arms, with attention to safety and improved quality of life:
 - Antiinflammatory treatment and prophylaxis of gouty arthritis. Treatment options are designed to either prevent acute gout flares or treat active inflammation of acute and chronic gouty arthritis.
 - Urate-lowering therapy. Treatment options aim to lower serum urate levels, as well as to achieve ultimate resolution of tophi and prevent the disabling tissue consequences of urate crystal deposition. Risk management of urolithiasis is an added objective in some.
 - Treatment of identified, significant comorbid conditions in patients with gout to bring about improved overall health and added, potential serum urate lowering and fewer acute gout attacks. Direct, pharmacologic treatment of asymptomatic hyperuricemia is not yet evidence based, but other measures to lower serum urate levels are appropriate.

TREATMENT OF ACUTE GOUTY INFLAMMATION

Therapeutic targets

Acute gouty arthritis is triggered by initial activation of resident cells, such as mast cells and synovial lining cells, and driven by monocyte ingress and a continuing cycle of neutrophil ingress and intraarticular neutrophil activation.³ Current evidence-based treatment strategies rely on broad inhibition (by nonsteroidal antiinflammatory drugs [NSAIDs], corticosteroids, and colchicine) of different combinations of cell adhesion to endothelium, phagocyte chemotaxis and activation, and expression and signaling by multiple mediators, including leukotriene B₄, interleukin-1 (IL-1), IL-8, and other inflammatory cytokines.³⁻⁵

Primary treatment objectives

The principal immediate goal of therapy in patients with acute gout is rapid, safe improvement in pain and inflammation. Long-term objectives include limiting recurrences of acute gouty arthritis and inhibiting chronic gouty synovitis and its associated connective tissue destruction. Treatment of both the pain and inflammation associated with acute gout is achieved with antiinflammatory agents. Other modalities (e.g., topical ice packs, acetaminophen, and in selected circumstances, opiates) are adjunctive measures.

Choice of drug and treatment regimens

Multiple effective drug options and dosing regimens for antiinflammatory treatment can be used for acute gout^{2,6-8} (Table 189.1). Selection of the appropriate option is influenced by the patient's comorbid conditions (e.g., renal, cardiac, hepatic, or gastrointestinal [GI] disease), drug interactions, attack duration, and number and accessibility to injection of the joints involved.² The typical response of acute gout to first-line options (NSAIDs,

systemic glucocorticosteroids, colchicine) is rapid but incomplete such that only approximately 50% pain reduction is achieved by 2 to 3 days in most subjects (grade A).⁹

Nonsteroidal antiinflammatory drugs

In appropriately designed clinical trials, multiple NSAIDs (e.g., Table 189.1) have been demonstrated to be effective for acute gout.² NSAIDs are typically given in full doses for at least 3 days and then tapered until the acute gouty arthritis subsides. GI and CNS side effects often limit the use of indomethacin. The author prefers naproxen to treat acute gout,⁶ but numerous other NSAIDs are effective alternatives²; those with a relatively short half-life are preferred. Some cyclooxygenase-2 inhibitors, such as etoricoxib⁹ and celecoxib, are effective for acute gout, but dosing and cardiovascular safety remain under review, as they are for NSAIDs. High-dose aspirin and non-acetylated salicylates are not recommended.

Corticosteroids

Prednisolone (30 to 35 mg daily for 5 days) appears to be at least comparable in efficacy and tolerance to NSAIDs in the first days of acute gout treatment.^{6,7} High starting doses of systemic antiinflammatory corticosteroids are needed for acute gout (e.g., ≥0.5 mg/kg daily for oral prednisone), especially with severe polyarticular flares.^{2,6,7} Triamcinolone (60 mg intramuscularly once) or a methylprednisolone dose pack can be used as starting therapy for acute gout.² The effectiveness of intraarticular injection of a depot corticosteroid for gout involving one or two large joints has been supported by small, open studies.² Initiation of adjunctive, daily low-dose prophylactic colchicine with systemic corticosteroids can inhibit the occurrence of rebound gout flares after stopping corticosteroid therapy that may be driven by corticosteroid induction of the inflammasome constituent NLRP3.¹⁰

Adrenocorticotrophic hormone

Adrenocorticotrophic hormone (ACTH) not only induces adrenal glucocorticosteroid production but also has a distinct peripheral antiinflammatory effect via the melanocortin 3 receptor.¹¹ ACTH is an effective option for acute gout in patients without preexisting adrenal suppression, particularly for those unable to ingest anything orally.² Synthetic ACTH is preferred to reduce the risk for hypersensitivity.

Colchicine

Clinical pharmacology of colchicine and drug-drug interactions

Via uptake in the jejunum and ileum, colchicine is readily bioavailable after oral administration. The lipophilic nature of colchicine facilitates cell uptake by allowing colchicine to bind tubulin, its primary target.¹² Colchicine is predominantly eliminated by biliary and fecal excretion. Extrusion of colchicine from cells (including gut-lining cells), enterohepatic recirculation, and marked drug enrichment in bile are critical for drug elimination, with ABCB1 (P-glycoprotein multidrug resistance transporter) playing a central role (Fig. 189.1).¹² Plasma membrane ABCB1 pumps multiple classes of substrates out of cells, thereby mediating multiple drug-drug interactions that can develop even with low colchicine doses (grade A).^{12,13} Clarithromycin and cyclosporine are examples of potent ABCB1 inhibitors.⁷ Most ABCB1 inhibitors also inhibit cytochrome P450 3E4 (CYP3A4), which carries out hepatic demethylation of colchicine to inactive metabolites before hepatobiliary excretion of the colchicine.^{12,13} Colchicine neuromyopathy can develop weeks after the initiation of cyclosporine.¹² Two macrolide antibiotics, clarithromycin and erythromycin, are known to promote serious colchicine toxicity, including death.^{12,13} In contrast, another macrolide, azithromycin, inhibits ABCB1 only weakly, does not significantly increase plasma concentrations of colchicine in healthy volunteers, and

TABLE 189.1
Therapeutic options for acute gouty inflammation

Drug option	Typical regimens
COX-nonselective NSAIDs (grade A evidence for each regimen listed)	Naproxen, 750-1000 mg PO daily for 3 days, then 500-750 mg total daily for 4-7 days Sulindac, 300-400 mg daily for 7-10 days Indomethacin, 150-200 mg PO daily for 3 days, then 100 mg PO daily for 4-7 days
Off-label use: COX-2-selective NSAIDs (grade A evidence for etoricoxib, a drug not approved in many countries)	Celecoxib, 800 mg then 400 mg on day 1, followed by 400 mg bid for 7 days
Systemic corticosteroids (grade A evidence for oral prednisolone, 35 mg daily for 5-6 doses; lower evidence grades for other regimens)	Prednisone, 30-60 mg daily for 3 days, then taper by 10-15 mg/day every 3 days until discontinuation Oral prednisolone, 35 mg daily for 5 days Medrol dose pack (for less severe flares) or to initiate therapy In an NPO patient: Triamcinolone, 60 mg IM once, with additional corticosteroid treatment as needed Methylprednisolone, 100-150 mg IV for 1-2 days
Intraarticular corticosteroids (grade C evidence)	Particularly useful for flares in a single large joint Triamcinolone acetonide preparations are especially useful Dose titrated to the size of the joint
Off-label use: synthetic ACTH (grade C evidence)	25 USP units of synthetic ACTH SC for less severe flares; 40 USP units IM or IV once for more severe flares (including larger joint flares and polyarticular gout) 1-2 repeated doses of synthetic ACTH at intervals of 12 hours are often required with each of these regimens
Oral colchicine (grade A evidence for U.S. FDA-approved regimen)	In the United States: to treat an early acute gout flare: 1.2 mg once followed by 0.6 mg in 1 hour, then 12 hours later, oral low-dose colchicine at prophylaxis doses until the acute gout attack resolves Outside the United States: 0.5 mg tid for several days is the EULAR-recommended dosing regimen Oral colchicine treatment of acute gout should be avoided in those already taking a maintenance low dose of colchicine
Off-label use: IL-1 antagonism (grade C for anakinra, grade A for canakinumab)	Use of anakinra (e.g., 100 mg SC daily for 3 days) for gout is not approved by the FDA

ACTH, adrenocorticotrophic hormone; COX, cyclooxygenase; EULAR, European League Against Rheumatism; FDA, Food and Drug Administration; IL-1, interleukin-1; IM, intramuscularly; IV, intravenously; NPO, nothing by mouth; NSAID, nonsteroidal antiinflammatory drug; PO, orally; SC, subcutaneously.

Fig. 189.1 Colchicine is readily bioavailable after oral administration via uptake in the jejunum and ileum, and the lipophilic nature of colchicine allows ready absorption by multiple cell types and binding to its primary target tubulin, which serves as a drug reservoir. Colchicine is predominantly eliminated by biliary and fecal excretion, with a major role played by extrusion of colchicine from cells mediated by the multidrug resistance transporter molecule ABCB1 (P-glycoprotein [P-gp]). Catalysis of demethylation of colchicine to inactive metabolites by enteric and hepatic cytochrome P450 3E4 (CYP3A4) and renal elimination normally play lesser but significant roles (<10%, and 10% to 20%, respectively) in colchicine metabolism. However, CYP3A4 and renal disposition of colchicine become more critical with certain drug-drug interactions that affect ABCB1 and with aging and hepatobiliary dysfunction. Importantly, colchicine undergoes hepatobiliary excretion against the bile-to-blood concentration gradient, mediated in part by ABCB1 and normally achieving at least 70:1 enrichment in bile relative to blood. Colchicine elimination driven by hepatic metabolism and intestinal excretion follows a first-order process, with enterohepatic circulation playing a substantial role. (Modified from Terkeltaub RA. Colchicine update: 2008. *Semin Arthritis Rheum* 2009;38:411-9, with permission.)

appears to be safe to use with colchicine.¹³ Both renal disposition of colchicine and CYP3A4 metabolism are more important in patients with hepatobiliary dysfunction and potentially in those with aging (because of decreased ABCB1 expression).¹² Finally, colchicine and multiple statins have the potential to synergistically potentiate myopathy (including rhabdomyolysis).¹²

Mechanism of action

Colchicine binds tightly to unpolymerized tubulin and forms a tubulin-colchicine complex that regulates microtubule and cytoskeleton function.¹²

Binding of the tubulin-colchicine complex at the ends of microtubules physically acts on elongation of the microtubule polymer.¹² Colchicine thereby regulates cell proliferation, signal transduction, gene expression, chemotaxis, and neutrophil secretion of granule contents.¹² Colchicine acts disproportionately on highly proliferating cells (e.g., bone marrow, GI tract lining).¹² It also concentrates in neutrophils, possibly related to low ABCB1 expression.¹² Nanomolar colchicine, achievable in plasma with low daily prophylactic doses of colchicine, suppresses E-selectin redistribution in the endothelial cell plasma membrane, thereby suppressing neutrophil adhesion.¹²

Evidence basis and colchicine dosing for treatment of acute gout

Oral colchicine is believed to be more effective when given in the first 36 hours of gout flares.² European League Against Rheumatism (EULAR) consensus guidelines for treatment of acute gout with colchicine call for a maximum of three colchicine (0.5 mg) tablets per 24-hour period (grade A).¹⁴ A large, randomized, controlled multicenter trial found that a low-dose colchicine regimen of 1.2 mg followed by 0.6 mg in 1 hour (1.8 mg total, patient administered within 12 hours of onset of the acute gout attack) was equally effective and much better tolerated than higher-dose colchicine (grade A).⁸ Based on pharmacokinetics,⁸ this regimen can be followed 12 hours later by prophylactic dosing of colchicine (see later) until the acute gout attack resolves.

Side effects

GI toxicity (diarrhea, sometimes severe, nausea, and to a lesser degree, vomiting) is the most frequent adverse event with oral colchicine.^{8,12} Bone marrow depression is common with colchicine overdose, with the nadir occurring 1 week after drug initiation. Cardiac toxicity with more severe overdosing can include arrhythmia. Cardiovascular collapse can occur as well. Colchicine overdose is also hepatotoxic and can cause alopecia. Colchicine myopathy, which affects proximal more than distal muscles and is accompanied by elevated creatine kinase in the early phase and by varying neuropathy, can mimic inflammatory muscle disease. Colchicine is, at most, weakly dialyzable. Severe cases of colchicine intoxication are treated by supportive care and can be lethal.¹²

Colchicine and other antiinflammatory drugs for prophylaxis of acute gout

Limitation of the subclinical joint inflammation in gout underpins the prophylactic effect of colchicine.¹² The most common adverse event on initiation of urate-lowering therapy (ULT) is acute gout flare (grade A).^{2,15} More intense ULT regimens precipitate more acute flares early in therapy, probably because of the local inflammatory effects of urate crystal deposit remodeling. For prophylaxis of acute gout, low-dose colchicine therapy is the first choice; it is commenced 1 week before initiation of serum ULT and typically continued for 6 months (if ULT is successful within that period) or until the clinically detected tophi resolve (grades A and B).^{1,2,16,17} Low-dose NSAID therapy is a sound alternative first-line choice if NSAID risk management is appropriate, although the evidence is limited.¹⁷ Low-dose prednisone therapy should be avoided but is sometimes necessary as a last resort.² The recommended dosage of colchicine is 0.6 mg twice daily in an average-sized younger patient with preserved renal and hepatobiliary function. Specific severe drug interactions (e.g., with clarithromycin, erythromycin, or cyclosporine) should be avoided.¹³ Low-dose prophylactic colchicine dosing should be reduced by 50% in patients with a glomerular filtration rate (GFR) lower than 50 and even more so in those with end-stage kidney disease.¹²

Drugs in clinical development for the treatment and prophylaxis of gouty arthritis

IL-1 β plays a more central role than tumor necrosis factor- α in urate crystal-induced inflammation (grade B).¹⁸ In refractory cases of gouty arthritis, the off-label use of IL-1 antagonists (e.g., the soluble IL-1 receptor antagonist anakinra, 100 mg daily subcutaneously for 3 days) has shown evidence of efficacy.¹⁸ IL-1 antagonists are in advanced clinical trials for the treatment (canakinumab) and prophylaxis (rilonacept) of acute gout, but the risk-benefit ratio is uncertain at this point.²

TREATMENT OF HYPERURICEMIA IN GOUT

Nonpharmacologic measures

In certain gout patients, serum urate can be improved or normalized by measures such as substitution of an alternative antihypertensive for a thiazide, better control of hypertension, reduction of obesity, appropriate moderation of specific portions in the diet, and limited consumption of alcohol, particularly beer.¹ Dietary advice to gout patients is often first tailored to their comorbid conditions, such as diabetes, atherosclerosis, hypertension, and chronic kidney disease (CKD).¹ A low-carbohydrate, weight reduction diet tailored to treat metabolic syndrome can lower serum urate levels, but only by approximately 18% at most (grade B).¹⁹ Broadly, purine-restricted diets are typically less effective than that and largely unpalatable, and ample vegetable consumption (including vegetables with high purine content) is

a valuable health measure that is associated with lower serum urate. Decreased consumption of high-fructose corn syrup-sweetened beverages (e.g., sodas, energy drinks) has potential salutary effects on hyperuricemia.¹ In patients with advanced CKD, it has been noted that hemodialysis significantly reduces body urate stores, and gouty arthritis often quiets down clinically in hemodialysis patients. Finally, asymptomatic hyperuricemia is not yet an evidence-based indication for direct pharmacologic treatment, except for prevention of tumor lysis syndrome.

Indications for pharmacologic urate-lowering therapy for gout and drug choices

Figure 189.2 presents an algorithm for pharmacologic urate-lowering therapy (ULT) in patients with gout and highlights the indications and choices. Gout ULT is most effective when continued indefinitely so that serum urate levels remain lower than 6.0 mg/dL.¹ Patient education is critical for ULT.²⁰ Conveying to the patient early in therapy that gout is caused by excessive body stores of uric acid and that only ULT is “curative” appears to facilitate appropriate adherence to and success of ULT²⁰ (grade B). Therapy goals and the risk-benefit ratio of treatment should be considered individually.¹ ULT should not be initiated until acute gouty inflammation is under adequate antiinflammatory control, but once established, the ULT should not be interrupted during acute gout flares. First-line pharmacologic ULT consists of targeting uric acid formation by xanthine oxidase inhibition

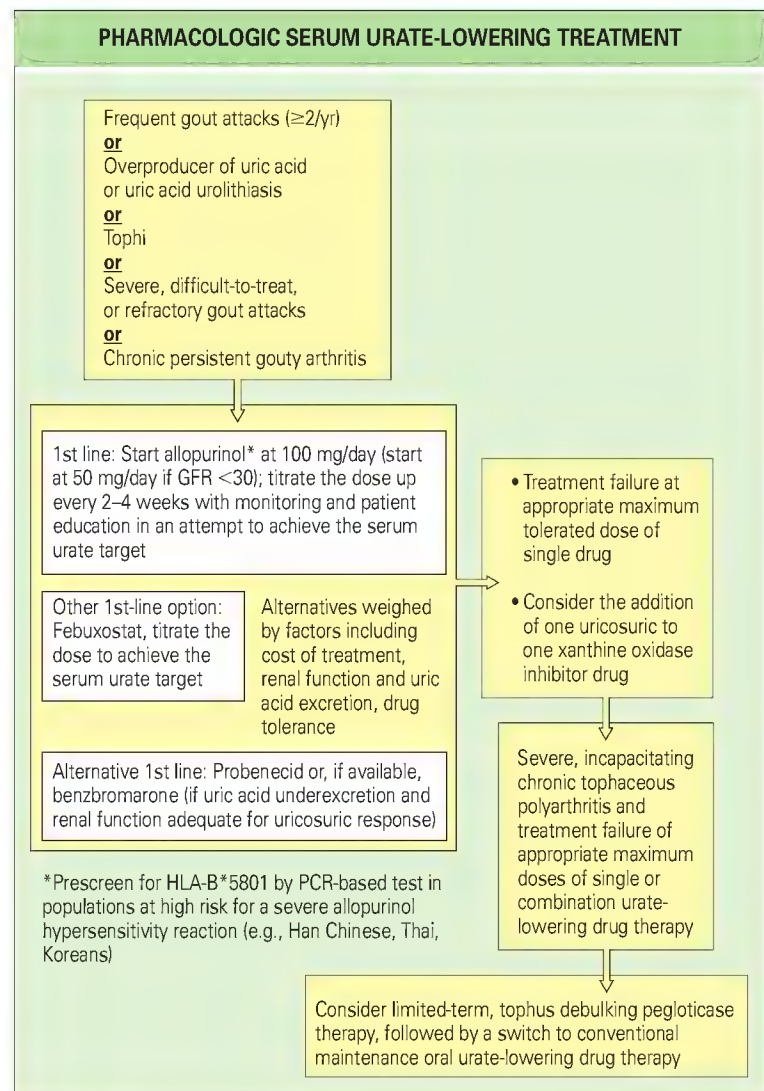

Fig. 189.2 Algorithm for pharmacologic serum urate-lowering treatment of hyperuricemia in patients with a confirmed diagnosis of gout. The algorithm, discussed in text, summarizes the first-, second-, and third-line approaches to pharmacologic urate-lowering therapy, including management of refractory hyperuricemia in difficult gout. GFR, glomerular filtration rate; PCR, polymerase chain reaction.

(XOI) with allopurinol or febuxostat^{1,15} (see Fig. 189.2). Because of large cost differences, allopurinol is often started first, with febuxostat substituted in those intolerant of allopurinol or failing maximum, appropriate doses of allopurinol despite adequate adherence to treatment. Monotherapy with a potent uricosuric is a sound alternative first-line approach in many patients (grade B),²¹ and probenecid is the most widely available drug with potent uricosuric action. Benzbromarone is a particularly potent and effective uricosuric,²¹ but hepatic safety issues have led to restrictions in availability and use of the drug, and it is not approved in the United States. Targeting the uric acid underexcretion that drives hyperuricemia in most patients can robustly decrease body urate stores.¹ However, effective urolithiasis risk management needs to be in place. Little published evidence is available on efficacy and safety of probenecid for stage 3 CKD, whereas benzbromarone remains effective for stage 3 CKD. Uricosurics should not be used in patients with a creatinine clearance of less than 30 mL/min.

Strategies for treatment-refractory hyperuricemia

Since effective XOI treatment robustly lowers total urinary uric acid excretion, addition of a uricosuric agent to patients with hyperuricemia refractory to XOI provides an additive serum urate-lowering effect (grades A and B).^{22,23} Probenecid is useful in this setting,²¹ as can be agents with less potent uricosuric effects, such as fenofibrate and losartan.¹ Fenofibrate can lower serum urate by up to 20%, an effect less potent than that of primary uricosurics but potentially useful as an adjunct in patients with hypertriglyceridemia. The uricosuric effects of losartan become maximal at 50 mg daily, but the urate lowering may be transitory, and in most patients losartan does not lower serum urate by more than 10%.

A serum urate target of less than 6 mg/dL (<360 mmol/L) is the minimum acceptable target level, with a lower level being appropriate for chronic tophaceous gouty arthritis. Beyond tophus debulking and fewer acute gout attacks, improved health-related quality of life and a reduction in functional, occupational, and social disability are ultimately achieved with effective ULT.¹ The solubility of urate in physiologic solutions is low (i.e., ≈6.7 to 7.0 mg/dL). Concordantly, current guidelines for decreasing total body urate stores, debulking and resolving tophi, reducing the ultimate frequency of gout flares, and decreasing the risk for ongoing precipitation of urate crystals support continuing (lifelong) reduction in serum urate to less than 6 mg/dL.¹ There may be salutary indirect or direct effects on renal function and blood pressure by achieving this target level in gout patients via XOI, potentially mediated by antioxidant effects or serum urate lowering.²⁴

More aggressive oral ULT to decrease serum urate to less than 4.0 mg/dL, including combining XOI and uricosuric treatment, accelerated the velocity of reducing tophus size by approximately 2 mm/mo for index tophi with mean size of 27 mm in one study²⁵ (Fig. 189.3). Achieving a serum urate level in the 0- to 4-mg/dL range is appropriate with moderate to severe chronic tophaceous gouty arthritis.¹ To do so, a more intensive and expensive “biologic” strategy, appropriate only for carefully selected, more difficult cases of severe or treatment-refractory chronic tophaceous arthritis, is to use intravenous pegloticase, a recombinant pegylated uricase that directly degrades urate (grade A).²⁵ This approach has the potential to rapidly decrease the miscible body urate pool size and resolve tophi in months rather than years with most XOI or uricosuric monotherapy.

Allopurinol

Clinical pharmacology and mechanism of action

Allopurinol undergoes hepatic conversion to the active metabolite oxypurinol, whose half-life is normally 24 hours.²⁶ This allows allopurinol, at doses of up to 300 mg/day, to be given once daily. Because of primary renal clearance of oxypurinol, its half-life rises substantially in those with renal impairment. Allopurinol and oxypurinol lower serum urate not only by inhibiting xanthine oxidase but also by competing for phosphoribosylpyrophosphate in the salvage pathway and by the suppressive effects of drug nucleotides on amidotransferase activity, the rate-limiting step in purine synthesis. Allopurinol nonselectively interferes with pyrimidine metabolism.

Side effects

Lack of selectivity of allopurinol contributes to a wide range of potential toxicities, with significant drug intolerance developing in about 5% to 10%, including dose-dependent GI side effects such as nausea or diarrhea, elevated liver transaminases in approximately 3% to 5%, and variable CNS side effects.²⁶ Severe allopurinol-associated hepatic disease (granulomatous hepatitis, cholestatic jaundice, and severe liver necrosis) can occur, but this

Fig. 189.3 Mean serum urate levels and the velocity of reduction of tophi have a linear relationship, and the rate of acceleration of tophus debulking increases to greater than 2 mm/mo when serum urate is lowered below 4 mg/dL ($r = -.62$, $r^2 = -.48$; $P < .05$). Subjects were treated with allopurinol, the potent uricosuric benzbromarone (a drug not available in the United States), or a combination of the two. (From Perez-Ruiz F, Calabozo M, Pijoan JL, et al. Effect of urate-lowering therapy on the velocity of size reduction of tophi in chronic gout. *Arthritis Rheum* 2002;7:56-60. Reprinted with permission.)

is rare.²⁶ Allopurinol induces rash, typically pruritic and maculopapular, in about 2% of patients. Pruritus alone is a classic premonitory sign of rash and by itself is a valuable indication for a previously informed patient to immediately stop taking allopurinol.²⁶ Bone marrow suppression is uncommon with allopurinol but may occur at higher doses. Allopurinol has major drug interactions with azathioprine, 6-mercaptopurine, and theophylline, whose metabolism is mediated by xanthine oxidase. Patients taking warfarin need careful observation of their anticoagulation status. In addition, ampicillin and amoxicillin trigger a rash in at least 20% of allopurinol-treated patients. Appropriate clinical practice is to periodically monitor the liver panel, chemistry profile, and eosinophil and other blood counts in conjunction with serum urate levels before and after allopurinol is initiated, especially in patients with CKD.

Severe allopurinol hypersensitivity reaction: clinical features and risk management

The constellation and clinical reporting criteria for major allopurinol hypersensitivity (AHS) reactions include severe cutaneous adverse reactions to allopurinol (such as Stevens-Johnson syndrome or toxic epidermal necrolysis) and drug reaction with eosinophilia and systemic symptoms (DRESS) (which can include severe multiorgan disease and combinations of vasculitis, various rashes, and hepatic and renal dysfunction, with approximately 20% to 25% mortality [grade B]²⁷) (Box 189.1). Risk factors (Table 189.2) include HLA-B*5801,²⁸ the starting dose of allopurinol, CKD,²⁷ and concurrent use of thiazide diuretics, which may act partly by increasing renal oxypurinol reabsorption.

The highest risk for AHS occurs in the first 60 days after initiation of allopurinol.²⁷ The direct toxic effects of accumulation of oxypurinol and T-cell activation responses to allopurinol and oxypurinol appear to contribute to the pathophysiology of AHS.²⁶ Recent studies show no association between the maintenance dose of allopurinol and the likelihood of AHS developing,²⁷ and maintenance doses of allopurinol below 300 mg daily do not achieve the serum urate target level in the majority of subjects.^{1,15} In contrast, adjusting the starting dose of allopurinol so that it is low (especially in those with renal impairment) and steadily titrating allopurinol

BOX 189.1 MAJOR RISK FACTORS AND PROPOSED CRITERIA* FOR ALLOPURINOL HYPERSENSITIVITY SYNDROME

Major risk factors

Starting dose of allopurinol higher than 1.5 (measured as the starting dose of allopurinol in milligrams per estimated GFR [mL/min]; e.g., a starting dose of allopurinol of 100 mg daily with an estimated GFR of 66 = 1.5)
Chronic kidney disease
Concurrent thiazide use
HLA-B*5801

General recommendations

1. Start allopurinol at no more than 100 mg daily in those with a GFR of 60 or higher, and increase by 100 mg every 2 to 4 weeks, along with patient education and monitoring, in an attempt to achieve the serum urate target
2. Decrease the starting dose to no more than 50 mg daily with an EGFR of 30 or less, and increase by 50 mg every 2 to 4 weeks in an attempt to achieve the serum urate target
3. The maximum FDA-approved maintenance dose is 800 mg daily
4. Progressively decrease the maximum allopurinol dose with progressively worse chronic kidney disease, but 300 mg daily can be exceeded with patient education and monitoring

Major criteria

1. Rash (e.g., diffuse maculopapular, exfoliative, toxic epidermal necrolysis, Stevens-Johnson syndrome, erythema multiforme). Some patients have more than one type of rash
2. Worsening renal impairment
3. Acute hepatocellular injury

Minor criteria

1. Fever
2. Eosinophilia
3. Leukocytosis

Criteria fulfillment

At least two major criteria or one major and at least one minor criteria or Rash only and/or more minor criteria
Renal only and/or more minor criteria

*Criteria reprinted with permission from Stamp LK, Taylor WJ, Jones PB, et al. Starting dose is a risk factor for allopurinol hypersensitivity syndrome: a proposed safe starting dose of allopurinol. *Arthritis Rheum* 2012;64:2529-36.
EGFR, estimated GFR; FDA, Food and Drug Administration; GFR, glomerular filtration rate.

TABLE 189.2
HLA-B*5801 and risk for allopurinol hypersensitivity syndrome

Population: HLA-B*5801 prevalence	Odds ratio for AHS with HLA-B*5801
Han Chinese: 9%	≈580:1
Koreans: 12.2%	≈380:1 with stage 3–5 chronic kidney disease
Thai: >6%	≈350:1
Whites: 1%–3% in most	Up to ≈80:1 (lower negative predictive value)

Meta-analysis: HLA-B*5801 and risk for AHS*

Matched control studies: OR = 96.60; 95% CI, 24.49–381.00; *P* < .001
Population control studies: OR = 79.28; 95% CI, 41.51–151.35; *P* < .001
Subgroup analysis for Asian and non-Asian population found increased OR

Recommendations by the author

1. HLA-B*5801 screening is appropriate for AHS high-risk/high-HLA-B*5801 prevalence groups (particularly Han Chinese, Thai, Koreans) by rapid, inexpensive PCR-based methodology (followed by PCR sequencing of inconclusive results, which typically occur in ≈10% of PCR screening tests for HLA-B*5801)
2. Populations at high risk for AHS continue to be defined
3. Those with a known positive HLA-B*5801 test should not receive allopurinol

*Samkrua R, Eichman EE, Saokaew S, Lahitnavy M, Chaiyakunapruk N. Association of HLA-B*5801 allele and allopurinol-induced Stevens Johnson syndrome and toxic epidermal necrolysis: a systematic review and meta-analysis. *BMC Med Genet*. 2011;12:118.
AHS, allopurinol hypersensitivity syndrome; CI, confidence interval; OR, odds ratio; PCR, polymerase chain reaction.

upward are core aspects of using the drug both safely and effectively (see Box 189.1).¹

The incidence of AHS is approximately 0.1% to 0.4%, apparently highest in Southeast Asian subpopulations. HLA-B*5801 is most common in Southeast and East Asians (up to ≈8%) and those of African ancestry (up to ≈4%), but it is only about 2% in most white individuals. The HLA-B*5801-associated hazard ratio for AHS is several hundred to one in Han Chinese and Thai, irrespective of renal function, and in Koreans with an estimated GFR of less than 60 (stage 3 CKD or worse).²⁸ The HLA-B*5801 hazard ratio for AHS is approximately 80:1 in white people studied to date, but the predictive value of HLA-B*5801 is substantially less in whites than in Southeast Asians.²⁸ The author recommends prescreening subpopulations at high risk for severe AHS via rapid and relatively inexpensive single polymerase chain reaction–based testing for HLA-B*5801 as an appropriate measure to consider^{11,28} (see Table 189.2).

Allopurinol dosing, including dosing in those with chronic kidney disease

Clinical trial data indicate that allopurinol (300 mg daily) lowers serum urate by about 33% in populations of gout patients in which about 25% to 30% have tophi on physical examination and serum urate is approximately 9.5 to 10 mg/dL, with largely intact renal function.¹⁵ Daily doses of allopurinol needed to normalize serum urate in the average patient are close to 400 mg (grade A).²⁹ However, allopurinol is frequently underdosed in clinical practice, particularly in those with CKD (i.e., the vast majority of allopurinol prescriptions are for ≤300 mg daily). Previous maintenance dosing guidelines for allopurinol in patients with CKD (calibrated for their estimated GFR) are not evidence based, fail to adequately treat hyperuricemia, and also fail to prevent many cases of AHS.²⁹

In “start low, go slow” dosing of allopurinol in patients with normal renal function, a starting dose of allopurinol of 100 mg daily is used in the average patient (in accordance with Food and Drug Administration [FDA] and rheumatology society guidelines).^{1,27} With a GFR lower than 30 mL/min, the allopurinol starting dose is reduced so that it is no higher than 50 mg/day.²⁷ As long as the drug is well tolerated, the author titrates the maintenance dose upward by 100 mg daily (with normal renal function, but only by 50 mg daily in those with a GFR <30) every 2 to 4 weeks after starting allopurinol²⁹ (see Fig. 189.2). This is done until the serum urate target level or an appropriate maximum dose of allopurinol is reached. Allopurinol has been approved by the FDA at a maximum dose of 800 mg daily. The author, in accordance with current guidelines,^{1,14} titrates allopurinol above the previous renal dosing adjusted recommendations and increases the dose to above 300 mg daily even with CKD, a strategy often effective in achieving the serum urate target level.²⁹

The “start low, go slow” recommendation for dosing of allopurinol can help reduce gout attacks in early ULT. Patient education and monitoring (e.g., serum urate level, liver function tests) include instructions to stop taking allopurinol immediately if pruritus or rash develops. However, long-term safety data for allopurinol dosages higher than 300 mg daily are sparse. Reduced maximum allopurinol doses in patients with CKD are strongly supported by retrospective analysis of renal function–adjusted dosing and allopurinol toxicities, in which adverse events increased with dosages higher than 400 mg/day and particularly so at higher than 600 mg/day calibrated to a creatinine clearance of 100 mL/min (grade B).³⁰

At doses of 300 mg daily or less, allopurinol is given once daily in the morning. Above 300 mg daily, the drug is divided into two daily doses to improve GI tolerance. Since adherence to allopurinol therapy is often poor in clinical practice (grade B),³¹ pill counts or measurement of serum oxypurinol levels can be helpful to confirm suspected nonadherence. Particularly with CKD, oxypurinol levels may need to be above the average therapeutic range to achieve adequate lowering of serum levels (grade B).³²

Febuxostat

Febuxostat is a selective inhibitor of xanthine oxidase that occupies the access channel to the molybdenum-pterin active site of the enzyme.³³ Unlike allopurinol and oxypurinol, febuxostat does not have a purinelike backbone (Fig. 189.4). Furthermore, febuxostat, unlike allopurinol, is metabolized primarily by oxidation and glucuronidation in the liver, and renal elimination plays a minor role in febuxostat pharmacokinetics. Febuxostat, unlike

COMPARISON OF ALLOPURINOL, OXYPURINOL, PURINE BASE, AND FEBUXOSTAT STRUCTURES

Fig. 189.4 The purine base hypoxanthine and subsequently xanthine (both pictured here) are oxidized by xanthine oxidase in the chemical reactions that generate uric acid. Xanthine oxidase is inhibited by allopurinol and its major, long-lived active metabolite oxypurinol (both pictured here). Oxypurinol has a half-life much longer than that of allopurinol (up to 24 hours in subjects with normal renal function; longer with renal impairment). Febuxostat (pictured) is a xanthine oxidase inhibitor that unlike allopurinol and oxypurinol, does not have a purinelike backbone.

allopurinol, does not affect pyrimidine metabolism and is not reincorporated into nucleotides.

Febuxostat is labeled in the United States for use at 40 mg once daily, and if serum urate levels do not become normalized after at least 2 weeks of therapy, the dose is increased to 80 mg once daily. In Europe and many other countries, febuxostat is approved at doses of up to 120 mg once daily. Febuxostat has been analyzed in randomized, large clinical trials in which a maximum dose of 300 mg of allopurinol was used as a comparator.^{1,15} Overall, both 80 and 120 mg febuxostat achieved the serum urate target level of less than 6 mg/dL more often than allopurinol, 300 mg daily, did.¹⁴ The results of serum urate lowering were comparable overall for allopurinol, 300 mg daily, and febuxostat, 40 mg daily, in those with normal renal function. In subjects with stage 2 to 3 CKD, 80 mg febuxostat daily achieved a serum urate target level of less than 6 mg/dL approximately twice as frequently as did renally dose-adjusted allopurinol (200 to 300 mg daily), and 40 mg febuxostat was superior to renally dose-adjusted allopurinol (grade A).³⁴ Adverse effects of febuxostat include rash in less than 2% and elevation of hepatic enzymes, diarrhea, and dizziness in small proportions of treated patients,^{15,34} but there does not appear to be cross-reactivity with allopurinol. Via XO1 by febuxostat, there is a potential for major drug interactions with azathioprine and 6-mercaptopurine.

Outcomes with febuxostat

At 1 year, gout flare rates declined comparably in patients treated with allopurinol, 300 mg daily, and febuxostat, 80 to 120 mg daily.¹⁵ In a small open-label extension study of patients with tophi who kept taking febuxostat, about half achieved elimination of the tophi by 2 years and more than two thirds by 5 years (grade B).³⁵

Probenecid

Mechanism of action

Primary uricosurics such as probenecid, as well as certain other drugs with less potent uricosuric activity (e.g., losartan), inhibit the urate anion exchanger SLC22A12, which is localized at the apical (brush border) membrane of the renal proximal tubule epithelial cell.³⁶ Probenecid also inhibits voltage-dependent urate anion reabsorption into the peritubular interstitium by SLC2A9 at the proximal renal tubular epithelial cell basolateral membrane.³⁷

Dosing recommendations and side effects

Probenecid is started at 250 mg orally twice daily and titrated up to 1000 mg twice daily in most patients and occasionally up to 3 g daily if

tolerated. The risk for urolithiasis with potent uricosuric monotherapy such as probenecid and benzbromarone can be 9% to 11%. All patients should be able to adequately hydrate themselves and increase oral hydration, particularly during early treatment. Inhibition of uric acid urolithiasis by urine alkalinization adds complexity to the treatment regimen. Uricosuric risk management requires 24-hour urine uric acid assays to rule out overproduction of uric acid,¹ which along with urolithiasis, is a contraindication to such monotherapy. Acidic urine pH is a major risk factor for urolithiasis in patients with gout, as is urine-undissociated uric acid concentrations higher than 20 mg/dL (roughly equivalent to >40 mg/dL total uric acid in acidic urine) before or while receiving uricosuric therapy (grade B).³⁸ Probenecid modifies the renal clearance of methotrexate, penicillins and cephalosporins, salicylates, indomethacin, ketorolac, heparin, zidovudine, nitrofurantoin, and certain other drugs. Low-dose acetylsalicylic acid does not appear to robustly block the antihyperuricemic action of probenecid.

The uricase pegloticase for refractory hyperuricemia in patients with severe, chronic gout

Mechanism of action

Uricase is the final catalyst of purine degradation in nonprimate mammals and lower primates, but uricase expression was lost in humans and higher primates in evolution. Uricases directly degrade relatively insoluble uric acid by catalyzing its conversion to highly soluble allantoin (Fig. 189.5) (grade A).²⁵ Although uricases generate 1 mol of the oxidant hydrogen peroxide for each mole of uric acid degraded (see Fig. 189.5), erythrocyte and plasma antioxidant defenses normally prevent plasma oxidative stress³⁹ and associated methemoglobinemia and hemolysis.

Pegloticase for refractory hyperuricemia of gout

Pegylation of the recombinant porcine-baboon uricase pegloticase results in a circulating half-life of days to weeks and decreases but does not eliminate immunogenicity.²⁵ Intravenous administration of pegloticase consistently produces a marked initial reduction in serum urate, but serum urate begins to increase over a several month period in a substantial fraction of patients.²⁵ Preinfusion of an antihistamine, acetaminophen, and a corticosteroid such as hydrocortisone (200 mg) is used to decrease infusion reactions to pegloticase.²⁵ In phase 3 studies of particularly severe gout (≈70% with visible tophi), intravenous pegloticase (8 mg every 2 weeks) lowered serum urate levels to less than 6 mg/dL in approximately 42% of subjects by 6 months.²⁵ Significantly, such treatment promoted complete resolution of one or more tophi in 20% of patients by 13 weeks and in more than 40% by 25 weeks.²⁵

Side effects

Even with the use of gout attack prophylaxis, acute gout flares are seen in up to 80% of pegloticase-treated patients in the first few months of treatment, with flares tapering off later.²⁴ Moderate to severe infusion reactions were common (8% to 11%) in phase 3 trials of pegloticase infusion.²⁵ Flushing, urticaria, and hypotension occurred in some and anaphylaxis in approximately 2%.²⁵ Pegloticase infusion reactions can also include severe muscle pain or cramping, driven by undefined mechanisms. Glucose-6-phosphate dehydrogenase (G6PD) deficiency should be screened for before use of pegloticase since uricases can induce methemoglobinemia or hemolysis, which is linked to G6PD deficiency in some but not all affected subjects. Caution with pegloticase is prudent in patients with congestive heart failure.

Antibodies to pegloticase

Antibodies to pegloticase frequently emerge as treatment evolves over the first few months.²⁵ For pegloticase these include IgM and IgG antibodies, which do not directly neutralize uricase enzymatic activity but adversely alter its pharmacokinetics and pharmacodynamics.²⁵ Such antibodies, seen in elevated titer in the majority of nonresponders but in few responders, are associated with infusion reactions.²⁵ Importantly, loss of the serum urate normalization response (i.e., below 6 mg/dL) to pegloticase on one or more occasions indicates that the drug treatment course should be stopped; about 79% of infusion reactions in phase 3 studies occurred after the serum urate normalization response was lost.²⁵ To avoid masking loss of pegloticase ULT activity, potent oral ULT must be stopped in those taking pegloticase.

Fig. 189.5 (Top) Uricases such as pegloticase oxidize sparingly soluble uric acid to an intermediate degraded to highly soluble allantoin, which is more readily excreted in urine. This chemical reaction generates 1 mol of hydrogen peroxide per mole of uric acid degraded. (Bottom) The uricase tetramer structure is modeled in panels a to c. The purified recombinant porcine-baboon uricase pegloticase is modified by covalent attachment of 9 ± 1 strands of methoxy-polyethylene glycol per enzyme subunit, as depicted in panel d. Pegloticase contains 36 strands of 10-kDa polyethylene glycol (PEG) per uricase tetramer. This measure prolongs the enzyme's half-life and reduces, but does not eliminate immunogenicity. (a) Cartoon model of the uricase tetramer based on the crystal structure of *Aspergillus flavus* uricase. Each subunit is shown in a different color (red, blue, green, or yellow). (b) Space-filling model of the *A. flavus* uricase tetramer showing the tunnel. (c) Space-filling model of the *A. flavus* uricase tetramer rotated around the vertical axis so that the tunnel is not visible. (d) The structures of the PEG strands (shown in various shades of gray) were generated with a computer program. The scale of panel d is about half that of panels a to c. Calcium pyrophosphate crystal-associated arthropathy

■ ABHISHEK ABHISHEK ■ MICHAEL DOHERTY

- Calcium pyrophosphate (CPP) crystal-associated arthropathy is characterized by locomotor conditions associated with CPP crystal deposition.
- Sporadic, familial, and metabolic disease-associated forms are recognized.
- It predominantly affects the elderly.
- Clinical findings include the following:
 - Acute, self-limited synovitis, which is termed acute CPP crystal arthritis (formerly “pseudogout”)
 - Chronic arthropathy, which shows an association and overlap with osteoarthritis
 - Chronic CPP crystal-associated inflammatory arthritis
- Target joints include the knees, wrists, shoulders, and hips.

HISTORY AND NOMENCLATURE

Adams (1857) is credited with the first description of articular cartilage calcification (chondrocalcinosis [CC]) in pathologic specimens.¹ With the advent of radiography, it became apparent that CC is common and occurs alone or in association with arthritis. Mandl (1927) emphasized the clinical and pathologic diversity of CC at the knee and distinguished primary (asymptomatic, bilateral, no cartilage damage) from secondary CC (symptomatic, localized, often posttraumatic with cartilage fibrillation). In 1957, Sitaj and Zitnan used CC as a diagnostic feature for arthritis in five Czech families and coined the term *chondrocalcinosis polyarticularis*. The observation that CC often preceded the development of radiographic damage in these families reinforced previous contentions that CC causes arthritis. Undoubtedly, a major milestone occurred in 1962 when McCarty and colleagues discovered nonurate crystals, identified by x-ray diffraction as calcium pyrophosphate (CPP) dihydrate ($\text{Ca}_2\text{P}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$), in the knee fluid of patients with acute synovitis and CC. The clinical similarity to gout prompted the term *pseudogout* for this new “crystal-induced arthropathy.”² Cadaveric studies subsequently established CPP as the most common, but not exclusive cause of CC, which resulted in the term CC often being used synonymously with CPP crystal deposition (CPPD). The perspective of CPP crystals as primary, causal agents in joint disease was readily supported by the demonstration of CPP crystals in patients with acute arthritis, *in vitro* evidence that CPP crystals are potent inflammatory agents, and induction of synovitis by injection of CPP crystals into normal joints. The finding of metabolic disease associations and various forms of familial predisposition reinforced the analogy to gout. Consequently, CPP crystal-associated arthropathy was separated into hereditary, metabolic disease-associated, and sporadic/idiopathic forms.

Following the initial descriptions of *pseudogout*, a variety of other clinical manifestations of CPPD were reported. Many appeared to mimic other forms of arthritis, thus encouraging the proliferation of numerous “pseudo” syndromes and a complex clinical classification: “pseudogout” (type A), “pseudo-rheumatoid arthritis” (type B), “pseudo-osteoarthritis” (with acute attacks, type C; without inflammation, type D), “lathanic or asymptomatic” (type E), and “pseudoneuropathic” (type F), to which other forms were added later.³ In an attempt to simplify matters, *calcium pyrophosphate dihydrate crystal deposition disease* (to incorporate all instances of CPP crystal deposition) and *pyrophosphate arthropathy* (for cases with both structural changes of osteoarthritis [OA], e.g., cartilage loss, osteophytes, and cysts,

and intraarticular CPP crystal deposition) were used. Recently, the European League Against Rheumatism (EULAR) developed a simplified terminology for CPP crystal deposition⁴:

- CPP crystals: the simplified term for calcium pyrophosphate dihydrate crystals (similar to “sodium urate” for monosodium urate [MSU] monohydrate crystals)
- CPPD: the umbrella term for all instances of occurrence of CPP crystals
- CC: cartilage calcification, identified by imaging or histologic examination—mainly but not always caused by CPPD
- Clinical presentations associated with CPPD:
 - Asymptomatic CPPD: no apparent clinical consequences
 - Acute CPP crystal arthritis: acute self-limited synovitis (replaces “pseudogout”)
 - OA with CPPD: CPPD in a joint that also shows changes of OA
 - Chronic CPP crystal inflammatory arthritis: chronic inflammatory arthritis associated with CPPD

EPIDEMIOLOGY

Prevalence

Data on the prevalence of CC are largely confined to the knees, wrists, and hips.⁵⁻¹⁰ CC is strongly associated with age, the prevalence being low in those younger than 50 years, but it rises from 10% to 15% in those aged 65 to 75 years to 30% to 60% in those older than 85 years. Previous reports suggested a female preponderance. This may be due to confounding by age and OA, and the age-specific prevalence does not differ between men and women.⁶⁻⁸ CC is reported in most countries and racial groups but appears to be less common in the Chinese and possibly in people from the Middle East.^{10,11} A community-based study of the prevalence of knee OA with CPPD gave an estimate of 2.4% (age, sex, and knee pain standardized for Nottingham, United Kingdom, residents older than 40 years).⁷

Predisposing factors

Age

Age is a major predisposing factor but the precise mechanism is unknown. Although overall levels of inorganic synovial fluid pyrophosphate (PPi) from normal knees does not increase with age, chondrocytes from older individuals secrete more PPi than do those from younger individuals on stimulation by transforming growth factor- β (TGF- β),¹² and several key enzymes and transport proteins involved in PPi metabolism and transport are upregulated in the elderly, thus suggesting that increased tissue levels of PPi may have a role. Age-related changes in cartilage matrix may also contribute.

Heredity

Several reports indicate increased familial risk, as well as ethnic variation in occurrence, both of which support a genetic predisposition.¹³⁻¹⁸ The pattern of inheritance of familial CC varies, although autosomal dominance is usual. Two familial phenotypes have been emphasized:

- Early onset (3rd to 4th decade): florid polyarticular CC and variable severity of arthropathy ranging from mild to destructive
- Late onset (6th to 7th decade): oligoarticular CC mainly confined to the knees and arthritis resembling sporadic OA with CPPD

The latter may be more common than recognized. The late onset of disease expression and geographic dispersal of families pose difficulties in this

respect. Recombination mapping in British, French, and Argentinian families with CPPD identified the CC gene 2 (CCAL2) on chromosome 5p15.¹⁹ This was subsequently identified as the ANKH (ankylosis human) gene. The other reported locus (CCAL1) in one American family with premature OA and CPPD is on chromosome 8q.²⁰ No specific gene has been identified at the CCAL1 locus, which spans a genetic interval of 30 cM (physical distance of 25 Mbp). A case-control study suggested that the -4 bp G-to-A transition in 5' untranslated region of ANKH that upregulates its expression is associated with apparently sporadic CC.²¹ However, a larger community-based sibling study suggested that there is no significant heritable contribution to apparently sporadic CC and to OA with CPPD.²² Thus, although hereditary CPPD exists, most patients have sporadic disease.

Association with metabolic diseases

Numerous metabolic disease associations have been suggested, but many reflect a chance concurrence of common age-related conditions, as suggested by negative results from controlled studies looking for previously reported associations with diabetes, hypothyroidism, uremia, and Paget disease.²³⁻²⁵ The strongest evidence for association relates to hyperparathyroidism, hemochromatosis, hypomagnesemia (as a result of renal loss, e.g., the Gitelman variant of Bartter syndrome, or gastrointestinal loss, e.g., short bowel syndrome, intestinal failure), and hypophosphatasia, which associate with both CC and acute CPP crystal arthritis.²³⁻²⁶ However, for rarer metabolic conditions, such as Wilson disease, evidence is necessarily limited to the occurrence of premature CC in just a few cases.²³ Other metabolic diseases, such as ochronosis and acromegaly, rarely associate with CC and acute CPP crystal arthritis, whereas familial hypocalciuric hypercalcemia does associate with CC. Hemochromatosis is the only metabolic disease that causes structural arthropathy with CPPD. CC is reported to be more frequent in young H63D homozygotes (<65 years) and old H63D/C282Y compound heterozygotes (>65 years) than in C282Y homozygotes of the high ferritin (HFE) gene,²⁷ thus implying variable penetrance of HFE mutations or suggesting that factors other than iron overload may be responsible.

Associations with metabolic diseases are explained through putative effects on PPI metabolism extrapolated largely from *in vitro* data.^{28,29} Mechanisms other than effects on PPI metabolism may also be operative. Bone and cartilage changes may be present, and CPPD may be mediated via alterations in cartilage matrix. Suggested mechanisms include the following:

- Reduced breakdown of PPI by tissue nonspecific alkaline phosphatase (TNAP) as a result of
 - Reduced levels of TNAP (hypophosphatasia)
 - Presence of inhibitory ions (calcium, iron, or copper in hyperparathyroidism, hemochromatosis, or Wilson disease, respectively)
 - Impaired complexing of PPI and Mg (hypomagnesemia)
- Enhanced nucleation of CPP crystals by increased iron (hemochromatosis) or copper (Wilson disease)
- Increased calcium concentration (hyperparathyroidism)
- Increased PPI production through stimulation of adenylate cyclase by parathyroid hormone (hyperparathyroidism)

ASSOCIATION WITH OSTEOARTHRITIS AND JOINT INSULT

The relationship between CPPD and OA remains unclear. The strong overlap with OA has led many to consider OA with CPPD to be a "subset" of OA itself. The dose-response relationship between the concentration of CPP crystals in knee synovial fluid and the severity of radiographic OA (Fig. 190.1) also supports this view.³⁰ However, this relationship is complex inasmuch as CPPD and OA are both associated with increasing age, which could be a confounding factor, and each can occur without the other. Nevertheless, there is convincing evidence for a strong association between OA and CC at the knee, wrist, and metacarpophalangeal (MCP) joints.^{7,31} A U.K. study confirmed an increased rate of radiographic OA in those with CC (age-sex-adjusted odds ratio [OR] of 2.1 at the patellofemoral joint and 2.0 at the tibiofemoral joint).⁷ This appeared to operate principally through an association with osteophytosis rather than joint space narrowing. Such observations have prompted the hypothesis that CPPD in the context of OA may act as a marker for individuals with a "hypertrophic" and thus potentially reparative tissue response to joint injury. That this may be a generalized skeletal response with a predisposition to both osteophyte and enthesophyte formation is suggested by small uncontrolled case

Fig. 190.1 Association of calcium pyrophosphate deposition with hypertrophic osteoarthritis.

series in which a higher than expected concordance of CC and vertebral hyperostosis is reported.³² The association between CC and OA may be joint specific. For example, a community-based study suggested that hip OA does not associate with CC at knee, hip, or symphysis pubis whereas knee OA does.⁸ Basic calcium phosphate (BCP) and CPP crystals frequently coexist in the same joint (see Chapter 191), and cartilage mineralization as a result of deposition of both CPP and BCP crystals ("mixed crystal deposition") in varying proportions is common in end-stage OA. Indeed, BCP crystals, particularly apatite, are universal in end-stage OA, whereas CPP crystals were present in 18% of knee joints and 10% of hip joints analyzed.^{33,34}

Several observations support a relationship between preceding joint insult and the subsequent development of CC, for example, the high frequency of CC (often localized, premature) in knees that have undergone surgery; the frequency of CPPD in lumbar disk fibrocartilage removed at revision surgery; and reports of localized OA with CPPD as a late complication of juvenile chronic arthritis, joint instability, or trauma.³⁵ Similarly, constitutional varus malalignment of the knee in early adult life predisposes to subsequent knee CC.³⁶ Controlled radiographic and synovial fluid surveys suggest an inverse correlation between CPPD and rheumatoid arthritis (RA).³⁷

Mechanism

The mechanisms that link CPPD and osteophyte formation remain speculative but may include shared chemical or mechanical predisposing factors. For example, TGF- β stimulates osteophyte formation and also enhances elaboration of PPI by hypertrophic chondrocytes, thus predisposing to pericellular CPP crystal formation.³⁸ The occurrence of atypical osteoarthritic radiographic features in patients with coexistent disease further suggests that the primary association of CPPD is with the hypertrophic tissue response or OA. The "amplification loop" hypothesis may explain the variable interrelationship between OA and CPPD (Fig. 190.2). This hypothesis suggests that CPPD may be enhanced by the tissue changes that accompany OA and that once formed, the CPP crystals hasten further joint damage via inflammatory and mechanical effects.³⁵

The characteristic distribution of joints with structural changes in patients with OA and CPPD versus those who have OA alone remains unexplained. Age and gender, however, could be important confounders in that the prevalence of both OA at different joint sites and CPPD varies markedly according to these factors. The glenohumeral joint, for example,

Fig. 190.2 The "amplification loop" hypothesis explains association between calcium pyrophosphate deposition and osteoarthritis.

may appear to be a target site for OA with CPPD because it becomes a common site for OA only in elderly people.

CLINICAL FEATURES

CC can be an incidental finding, but the common manifestations of CPPD are acute synovitis and chronic arthritis.^{3,35,39,40} Others are rare.

Acute calcium pyrophosphate crystal arthritis

This is the most common cause of acute monoarthritis in the elderly. Acute attacks may be the only manifestation of otherwise asymptomatic CPPD. In older, mainly female patients, however, they are often superimposed on chronic symptomatic arthropathy. Any joint may be involved, including the first metatarsophalangeal joint simulating gout ("pseudopodagra"), but the knee is by far the most common site (Fig. 190.3), followed by the wrist, shoulder, ankle, and elbow. Concurrent attacks in more than one joint are unusual (<10% of cases), and polyarticular attacks are rare. The typical attack develops rapidly and is associated with severe pain, stiffness, and swelling, maximal within just 6 to 24 hours of onset. As with gout, the patient may describe the pain as the "worst ever" and be unable to tolerate even light pressure from clothing or bedding. Overlying erythema may occur but is less common than in gout. Examination reveals a tender joint with signs of marked synovitis—increased warmth, a large or tense effusion, joint line tenderness, and restricted movement with stress pain. Pitting periarticular edema is common, especially in those with wrist, ankle, and midfoot involvement. Fever is common and occasionally marked. Elderly patients may appear unwell and mildly confused, especially with knee or multiple joint involvement. Acute attacks are self-limited and usually resolve within 1 to 3 weeks. Transient, less severe "petit" attacks are probably common but difficult to confirm. Most episodes develop spontaneously, but several provoking factors may precede the attack by 1 to 3 days (Box 190.1), the most common being a stress response to intercurrent illness or surgery.

Chronic arthropathy

Symptomatic patients are mainly elderly and female. Large and medium-sized joints are targeted, with the knees being the most frequently and severely affected site, followed by the wrist, shoulder, elbow, hip, and mid-tarsal joints (Figs. 190.4 and 190.5). In the hand, the MCP joints (particularly the second and third) are the most severely affected sites. Symptoms are often restricted to just a few joints, although single or multiple joint involvement also occurs. The chronic arthropathy associated with CPPD may be manifested as OA with CPPD or as chronic CPP crystal inflammatory

Fig. 190.3 Acute calcium pyrophosphate crystal arthritis affecting the knee. Seen here in an elderly woman with background osteoarthritis and calcium pyrophosphate deposition. Bloodstaining of synovial fluid is common in this situation.

Fig. 190.4 Osteoarthritis with calcium pyrophosphate deposition.

BOX 190.1 SITUATIONS THAT MAY TRIGGER ACUTE CALCIUM PYROPHOSPHATE CRYSTAL ARTHRITIS

Definite

- Direct trauma to a joint
- Intercurrent medical illness (e.g., chest infection, urinary tract infection, myocardial infarction)
- Surgery (especially parathyroidectomy)
- Blood transfusion, parenteral fluid administration
- Joint lavage

Possible

- Institution of thyroxine replacement therapy
- Intraarticular injection of hyaluronan
- Bisphosphonate treatment

Note: Most cases of acute calcium pyrophosphate crystal synovitis develop spontaneously.

arthritis. The two forms may coexist in different joints in the same patient, and a single joint may evolve from one to the other.

Osteoarthritis with calcium pyrophosphate crystal deposition

OA with CPPD targets the knees in particular and is characterized by chronic symptoms with or without acute attacks of crystal-induced inflammation. When compared with OA without CPPD, it may be associated with more inflammatory symptoms and signs (e.g., more stiffness and effusion) and an atypical distribution (e.g., involvement of the MCP, radiocarpal,

Fig. 190.5 Chronic arthropathy—common sites of involvement.

midcarpal, glenohumeral, ankle, and midfoot joints).⁴ Examination, particularly of elderly women, often reveals more widespread but asymptomatic OA changes. Generalized OA with Heberden nodes, for example, is common. Though less well documented, it is likely that asymptomatic OA with CPPD is also common in the 8th and 9th decades, as is asymptomatic OA.

Chronic calcium pyrophosphate crystal inflammatory arthritis

Chronic CPP crystal inflammatory arthritis is manifested as chronic oligoarthritis or polyarthritis with inflammatory symptoms and signs and occasional systemic upset (with elevation of C-reactive protein [CRP] and the erythrocyte sedimentation rate [ESR]); superimposed flares with the characteristics of crystal inflammation support this diagnosis. It should be considered in the differential diagnosis of RA and other chronic inflammatory joint diseases in older adults.⁴¹ Apart from signs of OA, which may be widespread, signs of synovitis may be present, such as increased warmth, joint line or capsular tenderness, stress pain, effusion, and marked soft tissue thickening. It is usually most evident clinically at the knee, radiocarpal, or glenohumeral joints.

NATURAL HISTORY OF CHRONIC CALCIUM PYROPHOSPHATE CRYSTAL DEPOSITION—ASSOCIATED ARTHROPATHY

The natural history of chronic CPPD-associated arthropathy is poorly documented. However, despite the presence of often severe symptoms and structural changes at initial evaluation, one 5-year hospital-based study suggested

that most patients have a benign course, particularly with respect to involvement of small and medium-sized joints.⁴² As expected, most symptom progression in this study occurred in large, lower limb joints, but even in severely affected knees (the usual site of occurrence), 60% showed stabilization or improvement of their symptoms. However, in another hospital-based prospective study of 350 knees with OA, the presence of synovial fluid CPP crystals or CC associated with radiographic progression, especially bone attrition (OR = 3.44; 95% CI, 1.97 to 6.02) and clinical deterioration, suggested that CPPD may be a marker for a poor prognosis in patients with knee OA.⁴³ Against this is a report suggesting that the presence of CC in patients with knee OA has a protective effect on joint space narrowing over a 2.5- to 3-year period.⁴⁴ This observation might be expected if the association between CC and OA is mediated by a predisposition to osteophytosis.⁷ Nevertheless, the occasional development of rapidly progressive arthropathy, particularly at the knee, shoulder, or hip, is well recognized. This is virtually confined to elderly women and is generally accompanied by severe night and rest pain and associated with a poor outcome.^{3,45,46} Some such patients have problematic recurrent hemarthrosis, particularly of the shoulder and knee; joint leakage may cause extensive bleeding, swelling, and bruising of adjacent tissues. Interestingly, the occurrence of rapidly destructive arthritis at the hip (without local CPPD) appears to be more common in patients with CPPD at other sites, although the mechanism for this is obscure.³⁵

Uncommon manifestations

Atypical arthropathy and axial involvement

Marked proximal stiffness accompanying glenohumeral and polyarticular involvement may rarely suggest polymyalgia rheumatica. Severe spinal stiffness, particularly in Czech, Chilean, and other familial forms, may be manifested as “pseudo-ankylosing spondylitis”; indeed, spinal ankylosis may occur in these Chilean families.⁴⁷ The putative association with diffuse idiopathic skeletal hyperostosis may further complicate this issue. Acute attacks in axial joints are difficult to confirm, and some self-limited spinal syndromes, described in relation to the periodontium (crowned dens syndrome)⁴⁸ and cervical and lumbar regions, may reflect acute CPP crystal attacks. Certainly in elderly subjects, acute self-limited meningitic episodes may occur in relation to CPPD in degenerative ligamenta flava and cervical disks; such deposits rarely associate with chronic myeloradiculopathy. Preferential deposition of CPP in the ligamenta flava at C3–C6 remains unexplained but corresponds to the level of greatest mobility.

Tendinitis and tenosynovitis

Acute inflammatory episodes have been described for the triceps, flexor digitorum, and Achilles tendons, and tenosynovitis has been reported in the hand flexors and extensors.⁴⁹ Tendinitis and tenosynovitis usually, but not inevitably occur in patients with intraarticular CPPD. Flexor tendon involvement may be associated with carpal tunnel syndrome and, less frequently, with combined median and ulnar nerve entrapment at the wrist, with the entrapment appearing to relate more to soft tissue factors than to structural arthropathy. Tendon rupture (hand extensors, Achilles) is a rare complication.

Bursitis

Olecranon, infrapatellar, and retrocalcaneal bursitis is a rare clinical manifestation that predominates in patients with widespread CPPD. It is thought most likely that CPP crystals migrate to bursal tissues from the adjacent cartilage and capsule of tendons rather than deposit *de novo* in soft tissues.

Tophaceous calcium pyrophosphate crystal deposition

Tophaceous (“tumoral”) CPPD is rare but has been reported in intraarticular or periarticular sites, including the temporomandibular joint, hand, cervical spine, foot, hip, acromioclavicular joint, knee, and elbow. Tophaceous CPPD is most common at the temporomandibular joint.⁵⁰ Lesions are solitary and usually develop in areas of chondroid metaplasia without predisposing metabolic abnormality or CPPD elsewhere. Malignancy is often suspected and the diagnosis follows examination of excised material. Rarely, bone erosion and destruction may occur with tophaceous CPPD (e.g., at the temporomandibular joint).

INVESTIGATIONS

Central investigations for diagnosis are (1) fluid and tissue analysis (primarily synovial fluid and rarely bursal or tenosynovial aspirates and biopsy material) for the presence of CPP crystals and (2) plain radiographs. Other

Fig. 190.6 Calcium pyrophosphate crystals in synovial fluid.

investigations may be undertaken to exclude alternative or coexisting arthropathy, and once the diagnosis is confirmed, further investigation for predisposing metabolic diseases may be indicated.

Fluid and tissue analysis

In acute CPP crystal arthritis, aspirated fluid is often turbid or bloodstained, with diminished viscosity and greatly elevated cell counts (usually >90% neutrophils). Macroscopic appearance, viscosity, and cell counts in chronic arthropathy are more variable and range from “inflammatory” to “noninflammatory.” The initial search for CPP crystals should be carried out under light microscopy (400× or 1000×) since most (80%) are nonbirefringent and may not be visualized under noncompensated polarized light microscopy.⁵¹ However, once a crystal is identified by its morphologic characteristics, it should be examined under polarized light to see whether it also displays birefringence.

CPP crystals are recognized primarily by their morphology, generally rhomboids or rods, occasionally acicular, and approximately 2 to 10 μm long. A minority also show weak positive birefringence and inclined extinction (15 to 20 degrees) under compensated polarized microscopy (Fig. 190.6). “Twinning” of crystals, with a chip left at one corner, is occasionally seen. CPP crystals are less readily identified and often less numerous than MSU crystals, and they can often be missed. A careful search in areas of cellular debris and fibrin, as well as examination of a spun deposit, may increase detection. Although the crystals are robust, early examination of fresh fluid avoids problems of dissolution and postaspiration artifact. The Diff Quik stain using eosin G and thiazine is as effective as wet mount examination for detecting CPP crystals and can facilitate delayed examination of stained slides for quality control checks for up to 12 months.⁵² Dried cytospin preparations of synovial fluid are also stable for long-term storage and delayed crystal analysis for up to 12 months.⁵³ This is particularly attractive since crystal detection rates improve with centrifugation, freezing of slides is not required, and subsequent staining is possible.⁵³

For histologic samples, neutral buffers should be used to avoid dissolution because crystals may readily be lost during decalcification (often done for tissue submitted with bone). Stains such as alizarin red S improve detection. As with other synovial fluid particles, identification by polarized light microscopy is associated with both false positives and false negatives. Identification via more definitive analytic means (e.g., infrared spectrophotometry, electron microscopic methods, x-ray diffraction) is ideal. However, such methods often require a high crystal load for analysis, are expensive, and take time. Therefore, for routine clinical purposes, polarized microscopy of fresh synovial fluid represents a convenient, rapid, and adequate compromise.

Imaging

Plain radiographic features

Radiographic aspects relate to both the calcification and arthropathy associated with CPPD.⁵⁴

Calcification

CC most commonly affects fibrocartilage (particularly the knee menisci, wrist triangular cartilage, symphysis pubis, and hip labrum) but also occurs in hyaline cartilage (particularly the knee, shoulder, and hip) as thick linear deposits parallel to and separate from subchondral bone (Fig. 190.7). Though occasionally localized to a single joint, such as one knee, CC usually affects several joints. If absent from the knees, wrists, hips, or symphysis pubis, it is unlikely to be present elsewhere. Capsular (“linear”) and synovial (“cloudy”) calcification is less common than CC and is generally most obvious at the MCP joints (Fig. 190.8) and the knee. Florid synovial calcification occasionally simulates synovial osteochondromatosis—most

Fig. 190.7 Knee radiograph showing chondrocalcinosis of both fibrocartilage (meniscus) and hyaline cartilage.

Fig. 190.8 Calcification affecting the metacarpophalangeal joints.

frequently at the knee. Deposition in tendon insertions particularly favors the Achilles (Fig. 190.9), triceps, and obturators and is typically linear and extensive, as opposed to the discrete nummular calcification of apatite.^{55,56} Diffuse calcification of bursae and ligaments may occur. Both CC and calcification are dynamic and may increase or decrease with time. CC may become less evident, particularly if cartilage thickness is lost or if crystals are “shed” during acute or recurrent inflammatory episodes.

Structural changes

The changes of CPPD with OA include cartilage loss, sclerosis, cysts, and osteophytes.^{35,54} Characteristics purported to aid distinction, however, include the following:

- Joint distribution and involvement within articulations that are atypical of OA (e.g., glenohumeral, MCP, ankle, or elbow; isolated or predominant involvement of the patellofemoral compartment; radiocarpal joint [sometimes with characteristic scapholunate dissociation]; midfoot (Fig. 190.10); or talocalcaneonavicular articulation)
- Often prominent, exuberant osteophyte (Fig. 190.11; see also Fig. 190.10) and cyst formation (Fig. 190.12), particularly at the knee and wrist.

Many cases of OA with CPPD appear to be similar to “uncomplicated” OA with respect to structural change (and vice versa), and a recent meta-analysis suggested that osteophytosis, joint space narrowing, and cysts do not specifically associate with coexistent OA and CPPD as opposed to OA alone.⁴ Sequential radiographic changes are variable. The few patients with destructive arthropathy show marked attrition of cartilage and bone with occasional fragmentation and loose osseous bodies that may resemble the “disorganization” of a Charcot joint; such cases may show rapid, progressive change (Fig. 190.13).

Marginal erosions are not a feature, although smooth “pressure” erosions (reflecting chronic effusions or bone “wear”) are not infrequent, particularly on the anterior aspect of the distal end of the femur and around the distal inferior radioulnar and radiocarpal joints. Patients with coexistent RA and

Fig. 190.9 Calcification of the Achilles tendon.

Fig. 190.10 Midfoot radiograph showing hypertrophic osteoarthritis. Note the prominent osteophytosis typical of osteoarthritis with calcium pyrophosphate deposition.

Fig. 190.12 Hand radiograph showing the typical radiocarpal involvement. Note the prominent cyst formation, chondrocalcinosis of the triangular ligament, and "pressure erosion" of the distal end of the radius.

CPPD may have a modified radiographic appearance (Fig. 190.14) characterized by retained bone density, prominent osteophytes, prominent well-corticated cysts, and a paucity of erosion (i.e., predominance of reparative OA rather than atrophic destructive change).³⁷

Arthropathy in patients with hemochromatosis may be accompanied by similar radiographic changes, although possible differentiating features include more widespread MCP joint involvement, with the greatest difference in involvement occurring in the fourth and fifth digits; radial hook osteophytes at the MCP joint; absence of scapholunate dissociation; involvement of the MCP joint in the absence of radiocarpal arthropathy; more frequent multiple "ring cysts" in large joints; and subchondral bone fragmentation at the hip.⁵⁷

Computed tomography

Computed tomography (CT) is particularly useful in the evaluation of CPPD in the spine. CT of the cervico-occipital junction may show periodontal calcification, subchondral cysts, and erosion in patients with crowned dens syndrome. Magnetic resonance imaging (MRI) may be used for further evaluation of patients with neurologic symptoms.

Fig. 190.13 Rapidly destructive knee arthropathy in an elderly woman. Note the marked bone attrition, bony "loose bodies," and chondrocalcinosis.

Fig. 190.14 Knee radiograph of patient with coexistent rheumatoid arthritis and calcium pyrophosphate deposition. On the anteroposterior view (a), widespread cartilage loss is evident, but the lateral view (b) shows marked new bone formation atypical of rheumatoid arthritis.

Ultrasound

High-frequency ultrasound (US) can demonstrate CPPD in hyaline cartilage and fibrocartilage and in and around tendons. CC appears as isolated or extensive linear hyperechoic deposits within the substance of hyaline articular cartilage and as rounded or amorphous deposits in fibrocartilage. In contrast, urate crystals are seen as hyperechoic linear deposits on the surface of articular cartilage. Articular CPP deposits are generally not dense enough to cast an acoustic shadow. Musculoskeletal US has high specificity (96.4% to 97.6%) and moderate to high sensitivity (68.7% to 86.7%) for the detection of CC at the knee⁵⁸ and performs better than plain radiography.^{4,59} However, MRI is relatively insensitive and detects only sizable CPP deposits.⁶⁰

Additional investigations

In acute CPP crystal arthritis, Gram stain and culture should always be performed on aspirated synovial fluid. Septic arthritis is the principal differential diagnosis, and concurrence with acute CPP crystal arthritis is reported. Other synovial fluid investigations are of little diagnostic value. Acute CPP crystal arthritis commonly triggers an acute-phase response consisting of elevation of plasma viscosity, ESR, acute-phase reactants (e.g., CRP), and the peripheral white blood cell count (predominantly neutrophils). Such changes are occasionally impressive, particularly with attacks affecting multiple large joints and in patients with triggering intercurrent illness.

In chronic CPP inflammatory arthritis, mild anemia with a modest elevation in acute-phase reactants (including ferritin) is not uncommon. The frequency of other biochemical and serologic abnormalities, however, is no different from that in other subjects of the same age.

Screening for predisposing metabolic disease

Metabolic disease predisposition is rare, and routine screening of all patients with CPPD is unrewarding. Nevertheless, CC and arthritis may be the initial feature of metabolic disease, and screening tests are warranted in the following circumstances:

- Early-onset arthritis (younger than 65 years)
- Florid polyarticular CC
- Recurrent acute attacks more than chronic arthropathy
- Presence of additional clinical or radiographic clues that suggest the diagnosis

Screening tests include calcium, alkaline phosphatase, magnesium, ferritin and transferrin saturation, and liver function tests.

DIFFERENTIAL DIAGNOSIS

Acute calcium pyrophosphate crystal arthritis

The occurrence of acute synovitis in one or a few joints, overlying erythema, pyrexia, systemic upset, and purulent joint fluid (particularly in the setting

of preceding surgery, trauma, or infective illness) should always lead to consideration and exclusion of septic arthritis. Because septic arthritis may coexist with crystal synovitis, Gram stain and culture of joint fluid should always be undertaken in an ill patient in a hospital setting (culture of blood and other body fluids may also be appropriate), even once CPP crystals are identified or radiographic CC demonstrated. Gout is the other principal condition to consider, with the diagnosis resting on synovial fluid analysis. Occasionally, heavy bloodstaining of joint fluid may lead to consideration of other causes of hemarthrosis, especially a bleeding disorder (low vitamin C levels in the elderly may encourage hemarthrosis) or subchondral fracture (particularly with preceding, provoking trauma). However, if CPP crystals are identified, results of the clotting screen are normal, no lipid is found in the aspirated fluid, and no radiographic fracture is present, the diagnosis of acute CPP crystal arthritis alone can be accepted. If localized tenderness and pain on weight bearing persist following the resolution of synovitis, repeated radiographs (with or without a subsequent bone scan) may be justified to detect missed fracture.

Chronic arthropathy

In most cases the characteristic distribution, radiographic features, and joint fluid findings permit a ready diagnosis. In older patients, however, a marked inflammatory component, polyarthritis with MCP joint involvement, and modest elevation of the ESR may lead to consideration of RA, particularly since large-joint involvement may predominate in elderly patients with RA. Nevertheless, the following considerations usually permit distinction: infrequency of metatarsophalangeal arthropathy, infrequency of tenosynovitis, absence of extraarticular features, lack of juxtaarticular osteopenia and marginal erosions, lack of strong seropositivity for rheumatoid factor and anti-CCP antibodies, and positive joint fluid and radiographic findings for CPPD-associated arthropathy.

Patients with marked proximal stiffness and an elevated ESR are differentiated from those with polymyalgia rheumatica mainly by careful locomotor examination and positive joint fluid and radiographic findings. Oral corticosteroids often improve the symptoms in such patients but rarely result in a rapid “cure” of polymyalgia; the response to local intraarticular corticosteroid may be more impressive. Differentiation from uncomplicated OA is often facilitated by the different pattern of distribution between and within articulations; the more florid inflammatory component; the presence of superimposed acute attacks; radiographic findings of an atypical distribution of joint involvement, CC, and prominent osteophyte and cyst formation; and synovial fluid CPP crystals.

Even though destructive CPPD arthropathy may resemble a neuropathic joint radiographically, such joints are severely symptomatic and arise in the absence of overt neurologic or serologic abnormality. Although the description of clinical manifestations by the addition of “pseudo” to other diagnostic labels suggests the close mimicry of other joint disease, the diagnosis is usually suspected on clinical grounds alone and confirmed by synovial fluid and radiographic findings. However, CPPD commonly coexists or is superimposed on other recognizable joint disease, thus making the prefix “pseudo” clearly inappropriate. The most common associated condition is OA (generalized, pauciarticular, or posttraumatic) affecting the same or distant joints, although coexistent gout, sepsis, RA, apatite-associated destructive arthropathy, or true Charcot arthropathy may all occur. In such cases the diagnostic label should reflect both conditions even though the relative contribution of each may vary at different sites in the same individual.

Though rare, tophaceous CPPD should be considered with malignancy and tophaceous gout in the differential diagnosis of calcified lesions involving periarticular soft tissues. Examination of biopsy material is required for correct diagnosis.

STRUCTURE AND FUNCTION

Pyrophosphate metabolism

Inorganic PPI is a byproduct of many biosynthetic reactions.⁶¹ Despite high turnover (about a few kilograms per day), both intracellular and extracellular concentrations of PPI are maintained at a low level by ubiquitous pyrophosphatases that metabolize PPI (complexed to Mg) to orthophosphate (Pi). Even with its high-energy phosphoester bond (implicated in the biochemical origin of life), PPI is not known to be an energy source in mammals, nor is it synthesized *de novo*.

Numerous biologic roles for PPI are now recognized, including participation in intracellular Ca²⁺ traffic, mediation of nucleotide and iron transport,

modulation of enzyme systems, storage of molecules in cellular granules, and effects on mitogenesis.⁶¹ In locomotor tissues, however, modulation of apatite mineralization is a key role.⁶² A certain level of PPi is required for the initial nucleation of apatite from amorphous calcium phosphate and for subsequent crystal growth. Paradoxically, a high level of PPi inhibits these processes by preventing nucleation and adsorbing to the surface of apatite crystals, thereby preventing further crystal growth.⁶² In a chicken embryo growth plate matrix vesicle model, CPP crystals formed exclusively when the Pi/PPi ratio was less than 6, and their formation was inhibited when the Pi/PPi ratio was higher than 28.4. In contrast, optimal formation of apatite crystals occurred when the Pi/PPi ratio was greater than 140 and their formation was completely inhibited when the Pi/PPi ratio was less than 70.⁶² This is how PPi inhibits abnormal calcification in the vasculature, saliva, and the urinary tract and is used industrially as a water softener.

Extracellular PPi (ePPi) may either be produced locally or result from the transport of intracellular stores. Because PPi cannot cross membranes passively, the multipass membrane transporter protein ANK regulates the passage of PPi to the exterior of the cell.⁶³ Loss-of-function defects in ANK can result in high intracellular PPi but low ePPi concentrations (Fig. 190.15). The subsequent low ePPi level promotes apatite formation and growth, which then results in abnormal mineralization of locomotor tissues—the “ankylosis” mouse phenotype from which the gene and its protein were first determined.⁶³ The ANKH gene (H = human) is the human homologue of ANK. Several ANKH mutations have been reported in familial CPPD, and it was proposed that the abnormality, instead of reducing, increases the activity of ANKH, which potentially results in high ePPi levels (see Fig. 190.15).^{19,21}

The family of phosphodiesterase nucleotide pyrophosphatase (PDNP) enzymes includes plasma cell membrane glycoprotein 1 (PC1, located on the cell membrane and matrix vesicles), autotaxin (secreted from cells), and PDNP3 (intracellular). All the PDNP enzymes hydrolyze the phosphodiesterase 1 bond of nucleoside triphosphates (NTPs).⁶⁴ The activity of surface 5'-nucleotidase may influence this reaction in favor of PPi production (Fig. 190.16). Of the three PDNP enzymes, PC1 is the most significant contributor to extracellular NTP, and studies in knockout mice suggests that PC1 and not ANKH is responsible for the majority of ePPi.⁶⁵

Adenosine triphosphate (ATP), the principal extracellular substrate for PC1, is released from chondrocytes following mechanical loading; during increased cell activity, cell division, and injury; and possibly during vesicular extrusion of matrix components and other products.^{61,66} Recently, ANKH has also been shown to export ATP.⁶⁷ The level of extracellular ATP together with PC1 activity determines ePPi levels and hence the possibility of CPP crystal formation.^{61,68} ePPi complexed with Mg is normally processed rapidly by surface TNAP to Pi, which can readily cross membranes. In organ culture,

adult hyaline cartilage and fibrocartilage, but not synovium or bone, elaborates ePPi. Increased PPi production occurs in growth plate cartilage and human OA cartilage.

The addition of ATP to cultured articular cartilage encourages CPP crystal formation, particularly around articular chondrocyte vesicles (ACVs).⁶⁸ These vesicles, analogous to the matrix vesicles of growing cartilage, are trilaminar, phospholipid membrane-limited structures adjacent to chondrocytes. They avidly bind calcium and are rich in all the enzymes that generate PPi and Pi. Cultured ACVs mineralize in the presence of calcium and ATP.⁶⁹ Depending on the PPi/Pi ratio (excess ATP producing a high ratio and restricted ATP producing a low ratio), ACVs produce CPP, BCP, or both types of crystals.^{62,69} Factors other than the ATP concentration can also influence ePPi elaboration in cartilage (Table 190.1). Frequently, complex mechanisms underlie these effects. For instance, the TGF- β -induced increase in ANK expression is mediated by the influx of Pi through the type III Na⁺/Pi channels PiT-1 and PiT-2 and by the influx of calcium by L-type or T-type voltage-dependent calcium channels—Ca²⁺ being required for the activation of extracellular signal-regulated kinase 1 and 2 (ERK1/2) and protein kinase C.^{70,71} Several other cell-signaling pathways may be of

relevance in moderating such responses; for example, protein kinase C activation stimulates and adenylyl cyclase stimulation diminishes PPI elaboration.⁷² Type 2 transglutaminase and factor XIIIa, both expressed in chondrocytes, increase CPP crystal formation.⁷³ This may be due to transglutaminase-mediated incorporation of latent TGF- β into the extracellular matrix and its activation, with post-translational modification of the extracellular matrix favoring crystal formation and stimulation of phospholipase A₂ leading to cartilage degradation and inhibition of TNAP.⁷⁴⁻⁷⁶ Dexamethasone increases the transcription of transglutaminase XIIIa, which leads to CPP crystal formation by cultured ACVs.⁷⁷ Osteopontin, a calcium-binding matricellular protein present in the pericellular location, also increases CPPD by activating transglutinases.⁷⁸

When compared with normal knees, elevated synovial fluid PPI concentrations are reported in both OA with CPPD and uncomplicated OA,⁶¹ the normal plasma and urinary concentrations in such cases supporting increased intraarticular production. Less impressive elevations in synovial fluid PPI are seen in acute CPP crystal arthritis, with subnormal levels in RA.⁶¹ These lower levels perhaps reflect increased clearance of PPI in inflamed states. Extracellular ATP, the major substrate for PPI, has been found in synovial fluid, with higher levels in OA with CPPD than in OA or RA.⁶¹

Pi and PPI levels are interrelated by several biofeedback mechanisms to maintain a physiological Pi/PPI ratio. For instance, a gain in ANKH activity increases the expression of PiT-1 and consequently results in high intracellular Pi levels, which then stimulates TNAP production, thereby lowering the ePPI concentration and promoting mineralization with hydroxyapatite.⁷⁹ Additionally, elevated extracellular Pi increases the effect of TGF- β on ANKH, PC1, and PiT-1 mRNA and protein expression, which increases ePPI.⁸⁰ The coexistence of BCP and CPP crystals in the same joint may be due to dynamic changes in the Pi/PPI ratio and result in the formation of both types of crystals.

Calcium pyrophosphate crystal formation

Factors likely to affect the formation, growth, and dissolution of CPP crystals are outlined in Figure 190.17. The formation of CPP crystal appears to be restricted principally to fibrocartilage and hyaline cartilage (less commonly the capsule and tendon), with only 2 of 12 known crystallographic forms occurring—the triclinic (t-CPP) and monoclinic (m-CPP) dimorphs. Unlike MSU crystals, which readily form in supersaturated solutions, CPP crystals require exacting conditions for formation. In addition, CPPD occurs

only in larger animals such as primates and dogs and does not occur in smaller animals. Thus, to date no animal model has been developed, and most knowledge has been derived from model systems using gels (nonbiologic gelatin or native collagen gels). From these systems the following generalities are implied. In addition to the product ($\text{Ca}^{2+} \times \text{PPI}$), the local Mg concentration importantly influences CPPD by inhibiting nucleation and growth and by enhancing dissolution. Pi, chondroitin sulfate, and proteoglycan are also inhibitory to nucleation and growth. With proteoglycan this effect depends on the spatial arrangement of carboxylate ligands, which may operate via calcium binding or spatial regulation of Mg, phosphate, or unidentified small-molecular-weight promoters and inhibitors.

Conversely, nucleating and growth-promoting factors include iron ($\text{Fe}^{3+} > \text{Fe}^{2+}$) and seeded MSU crystals. Interestingly, seeded apatite efficiently traps PPI, thereby leading to more stable CPP growth. A possible promoting role of collagen and acidic phospholipid has been suggested. Formation of m-CPP and t-CPP is slow and occurs via intermediate crystal species, with t-CPP being the final, most stable form.

Histologic studies suggest that CPP crystals form extracellularly in the pericellular area in the midzone of fibrocartilage and hyaline cartilage.⁸¹ A close association is reported with hypertrophic or metaplastic chondrocyte phenotypes containing Sudan-positive lipid granules, and similar lipid may occur around CPP crystals, the involved matrix often being depleted of proteoglycan and degenerate.⁸¹ Such findings support the importance of tissue (“soil”) factors, which implies that a reduction in inhibitors (e.g., proteoglycan) and an increase in promoters (e.g., lipid) combine to promote CPP crystal formation. Conversely, elevation of synovial fluid PPI, perhaps released from hypertrophic and metabolically active chondrocytes, argues in favor of “seed” components. The relative importance of these multiple factors may vary from time to time. With respect to dissolution, CPP crystals are extremely insoluble but can, however, be dissolved by TNAP. Mg enhances dissolution via both enzyme stimulation and enhanced release of PPI ions from the crystal surface.

PATHOGENESIS

Crystal-associated inflammation

Crystals of CPP, as with MSU, have been studied mainly in relation to acute inflammation.⁸² In general, laboratory-prepared CPP crystals are markedly phlogistic particles in a wide variety of *in vitro* and *in vivo* systems, though less so than MSU on an equal-weight comparison. Effects on humoral mediators, cytokines, cell-derived mediators, and cell membranes have been demonstrated.⁸² For example, CPP crystals activate complement *in vitro* via the classical and alternative pathways. Consequently, elevated synovial fluid complement breakdown products (C3d) occur with acute CPP crystal arthritis, though interestingly not with chronic arthropathy despite the presence of often marked clinical inflammation. Hageman factor is also activated and leads to the generation of kallikrein, bradykinin, plasmin, and other soluble mediators. A dramatic effect of CPP crystals is marked perturbation of plasma membranes, which causes membranolysis, as well as nonlytic platelet and neutrophil secretory responses. CPP crystals induce superoxide production by neutrophils and release of lysosomal enzymes, chemotactic factors, and lipoxygenase-derived products of arachidonic acid, including leukotriene B₄, following phagocytosis. CPP crystals engage the caspase-1-activating NALP3 inflammasome. This increases the production of interleukin-1 β (IL-1 β) and IL-18 by facilitating maturation of their precursors. CPP crystals appear to be equipotent to MSU crystals in activating the NALP3 inflammasome.⁸³ IL-1 β stimulates secretion of tumor necrosis factor- α and is chemotactic to neutrophils. Other CPP-cell interactions include the release of newly synthesized IL-6 from synoviocytes and monocytes (in accord with the high synovial fluid IL-6 levels demonstrated in acute CPP crystal arthritis). CPP crystals stimulate the ERK1/2 and p38 mitogen-activated protein kinase pathways and thereby result in the secretion of IL-8, which is important in neutrophil recruitment and activation. CPP crystals inhibit neutrophil apoptosis by inhibiting proapoptotic cysteine protease caspase-3 and activating ERK1/2, p38, and Akt.⁸⁴ This may explain the prolonged neutrophilic inflammatory response seen in patients with acute CPP crystal arthritis. CPP crystals activate Toll-like receptor 2 on the surface of articular chondrocytes, which leads to several changes (e.g., nitric oxide [NO] production) that may adversely affect the chondrocyte and the cartilage matrix.⁸⁵

Many of these effects result from direct crystal contact, although some (e.g., the classical pathway of complement activation) may be enhanced or mediated by adsorption of IgG onto the crystal surface (Fig. 190.18).⁸⁶ In biologic systems, CPP crystals avidly attract both anionic and cationic

Fig. 190.17 Possible factors influencing calcium pyrophosphate crystal formation.

Fig. 190.18 Potential interactions and blocking at the crystal surface are shown.

proteins, with some preferential selection for immunoglobulin, especially IgG. Although the altered stereochemical configuration of adsorbed IgG may be proinflammatory, other protein binding may be inhibitory. Of most interest in this respect are apolipoprotein B-containing low-density and high-density lipoproteins, binding with which, for example, inhibits CPP-induced neutrophil lysis.

Certain physical characteristics of CPP and other crystals appear to relate to their inflammatory potential. In general, smaller crystals are more inflammatory than large ones and m-CPP crystals are more inflammatory than t-CPP crystals; this may result from mechanical effects (e.g., greater ease of phagocytosis) or merely reflect the greater surface area or weight presented for protein or membrane interaction. “Roughness” and net negative surface charge are also important. The crystal surfaces of inflammatory membranolytic crystals (MSU, CPP) are irregular and possess a high density of charged groups that give a high negative zeta potential, whereas the surfaces of noninflammatory crystals (diamond, stishovite) are smooth, with low or zero zeta potential; brushite and apatite are intermediate in these respects and are associated with more modest inflammatory effects.

Less is known of the tissue damage induced by chronic CPPD, although postulated mechanisms include matrix metalloproteinase expression, NO release, persistent synovial inflammation, altered cell metabolism, prostaglandin E₂ release, and altered osteoblast activity.⁸⁵ Intradermal injection of CPP causes a chronic “granulomatous” reaction that lasts several weeks; unlike acute inflammation, CPP is more potent than MSU in this respect.

Mechanical effects of crystals

Deposition of hard CPP crystals within the cartilage matrix might theoretically be disadvantageous for cartilage but might equally facilitate the transmission of impact forces, depending on the shape, size, extent, and orientation of the crystals.⁸⁷ However, the occurrence of free crystals at the cartilage-cartilage interface is likely to be damaging through their effects as “wear” (abrasive) particles.⁸⁸ Though usually cleared quickly from synovial fluid, the presence of even a small amount of CPP crystals may thus be more harmful than much larger deposits within cartilage.

Crystal shedding

Given the difficult physicochemical requirements for *in vitro* manufacture, nucleation and growth of CPP crystals in synovial fluid would seem unlikely, and the preferred mechanism to explain the occurrence of CPP crystals within synovial fluid is “shedding” from preformed deposits within cartilage.⁸⁹ This could be accomplished by a reduction in crystal size, fissuring of cartilage, or an alteration in the cartilage matrix that allows easier escape of the crystals. Circumstantial evidence to support each of these possibilities includes the provocation of acute attacks by the following:

- Joint lavage with crystal-solubilizing agents or situations (acute stress response, parathyroidectomy) associated with a reduction in ionized calcium (reduced crystal size)

Fig. 190.19 The preformed calcium pyrophosphate (CPP) crystals initiate an acute attack but then become coated with protein and are processed by synoviocytes and inflammatory cells.

- Trauma (microfissuring, “shaking loose”)
- Thyroxine replacement (change in the cartilage gel matrix)
- Concurrence of acute CPP crystal arthritis and sepsis (“enzymatic strip mining”)

More direct evidence comes from the reduction in radiographic CC documented during acute CPP crystal arthritis and during follow-up of CPPD patients.^{39,89} Shedding from cartilage deposits might expose previously protected “naked” crystals to soluble mediators and cells and thus trigger the acute attack (Fig. 190.19). The CPP crystals are subsequently taken up and processed by neutrophils and synoviocytes; such “trafficking” through the joint, however, is slow, and CPP crystals are still identifiable in synovial fluid as the attack settles. What “turns off” the attack and permits inflammatory crystals to reside in synovial fluid during noninflamed intercritical periods remains unexplained. Nevertheless, coating by inhibitory proteins (some acute-phase reactants) appears to be more plausible than altered responsiveness or changes in the physical properties of CPP crystals.

PATHOLOGIC CHANGES

Unlike MSU, CPP crystals are not deposited in all connective tissues but are virtually confined to locomotor structures. Pathologic data largely support primary deposition in cartilage (less commonly, capsule, tendon, and ligament), with secondary release and uptake by synovium, tenosynovium, or bursae.

Microscopy of cartilage usually shows rounded, sharply demarcated crystal deposits within a granular matrix in the midzone.⁸¹ The earliest lesions are perilacunar, but with widespread CC, superficial cartilage may be involved, with tophus like deposits predominating in the midzone. Electron microscopy studies may dislodge CPP crystals, and those visualized often appear vacuolated and “foamy” (artifactual) with a bumpy contour, perhaps representing adsorbed protein. The surrounding cartilage may appear normal or show loss of metachromasia, chondrocyte cloning, or fibrillation; the occurrence of associated lipid-laden hypertrophic metaplastic chondrocytes has been particularly emphasized.⁸¹ With severe cartilage changes, subchondral bone may show thickened trabeculae with multiple cysts; cyst fracture occasionally results in bone fragmentation and collapse. In synovium, CPP crystals usually occur superficially in the interstitial space and synoviocyte vacuoles and are often surrounded by fibrocytes and connective tissue; neutrophil and lymphocyte infiltrates may be present, but the prominent response is lining cell hyperplasia. Tophus like deposits, surrounding giant cell reactions, and osteochondral bodies are occasional findings. In advanced disease, masses of CPP crystals may virtually replace ischemic-appearing villi. Changes in bursae and tendon sheaths resemble those in synovium.

MANAGEMENT

Recently, EULAR has developed consensus-driven, evidence-based guidelines for the management of CPPD.⁹⁰ Unlike gout, no treatment is available to reduce the CPP crystal load. Lavage with calcium-chelating agents (e.g., MgSO_4) provokes acute CPP crystal arthritis, perhaps through partial dissolution, which then encourages crystal shedding, and no compound capable of dissolving CPP crystals has come into use. Treatment of any underlying metabolic disease is appropriate. However, other than possibly for correction of hypomagnesemia, such treatment does not influence the outcome of CPP crystal-associated disease.

Acute calcium pyrophosphate crystal arthritis

The aims are to reduce symptoms, identify and treat triggering illness, and rapidly mobilize patients once the inflammation has settled. Rapid mobilization is important because many patients are elderly and prone to complications from prolonged immobility. In general, therefore, local rather than systemic therapy is preferred, particularly because acute CPP arthritis commonly affects only one or a few joints.

Aspiration and injection

In most cases, aspiration alone greatly relieves the symptoms and may be the only treatment required. Fluid reaccumulation, however, is common, particularly early in the attack. Therefore, for florid attacks, intraarticular injection of a long-acting corticosteroid is appropriate, either at the time of initial aspiration or as a second procedure following reaccumulation (some prefer the reassurance of a negative Gram stain or culture, or both, before injecting corticosteroid if septic arthritis is suspected). Joint lavage (normal saline, room temperature) can help settle attacks but is usually reserved for troublesome relapsing or prolonged episodes unresponsive to corticosteroid injection. Evidence for these treatments is anecdotal.

Other treatments

Ice packs may be applied for relief of symptoms. Simple analgesics and nonsteroidal antiinflammatory drugs (NSAIDs) may have additional benefits. NSAIDs are often contraindicated in the elderly. Oral colchicine may be effective but is rarely warranted; if used, it should be given at a low dose (e.g., 0.5 or 0.6 mg twice or three times daily) to reduce the incidence of gastrointestinal side effects, especially in elderly patients or in those with renal impairment. One small study of patients with recurrent acute CPP crystal arthritis ($N = 10$) suggested that colchicine may be effective in the prophylaxis of recurrent acute attacks.⁹¹ As for gout, colchicine, a microtubule assembly inhibitor, may work by inhibiting CPP crystal endocytosis or its presentation to the inflammasome.⁸³ In an elderly patient with acute CPP crystal arthritis, short courses of systemic corticosteroids may be preferred over NSAIDs and colchicine (once infection has been excluded as a trigger) and produce more rapid relief than possible with these oral agents.⁹² This approach is particularly suitable for severe polyarticular attacks unresponsive to aspiration and injection of the largest affected joints. In general, however, evidence for the use of pharmacologic agents is derived from observational and small controlled studies or by extrapolation from studies of patients with gout.

Anakinra (IL-1 receptor antagonist) has been used for the treatment and prophylaxis of polyarticular acute CPP crystal arthritis unresponsive to oral corticosteroids,⁹³ although the usefulness of this agent for prophylaxis was not confirmed in a recent case series consisting of just three patients.⁹⁴

Osteoarthritis with calcium pyrophosphate deposition

The aims of management and the choice of interventions are the same as for OA. A variety of strategies may be beneficial, although evidence for these

measures is extrapolated from OA trials (Chapter 181). Whether the presence of CPPD is a predictor of response to individual treatments of OA, however, has not been formally examined in clinical trials.

All patients should receive the following:

- Education concerning the nature of their arthritis
- Advice regarding both local strengthening and aerobic/fitness exercise
- Interventions aimed at minimizing adverse mechanical factors, such as reduction in obesity and appropriate footwear
- Simple analgesics such as paracetamol and topical NSAIDs, especially for the knee and hand

Recognition and management of depression and the use of coping strategies are applicable. Despite the presence of frequently marked structural abnormality, intraarticular corticosteroid injection often greatly improves the symptoms. Though often temporary, this may improve the patient's optimism, encourage adherence to other aspects of treatment, and provide a useful interval for effective physiotherapy or enjoyment of an important life event (e.g., holiday). One small, double-blind, placebo-controlled study reported a reduction in pain with oral magnesium.⁹⁵ However, no reduction in radiographic CC was found. A double-blind controlled study of intraarticular radiocolloid (yttrium 90) for CPPD with OA of the knee showed efficacy even in those with gross structural change.⁹⁶ The number needed to treat (NNT) was 2 for greater than 33.3% improvement in knee pain and 50% improvement in global knee symptoms. Radiosynovectomy is also useful for recurrent hemarthrosis, presumably by inducing synovial fibrosis.

Chronic calcium pyrophosphate crystal inflammatory arthritis

Oral NSAIDs (with gastroprotection) or colchicine (or both), low-dose corticosteroids, methotrexate, and hydroxychloroquine have been suggested as pharmacologic options for the treatment of chronic CPP crystal arthritis.⁹⁰ The use of NSAIDs and low-dose corticosteroids is based mainly on expert opinion. The use of colchicine is based on the findings of a study of patients with knee OA and persistent inflammation as a result of CPP crystals, in whom colchicine (0.5 mg twice daily for 8 weeks and then as necessary) resulted in greater than 30% improvement in pain (NNT = 2 at 4 months and 4 at 5 months). One small, double-blind, placebo-controlled study reported clinical benefit with oral hydroxychloroquine (NNT = 2 for a 30% reduction in swollen and tender joint counts).⁹⁷ In a retrospective review of patients with chronic CPP crystal inflammatory arthritis, methotrexate (median dose of 12.5 mg/wk) reduced symptoms, joint inflammation as assessed clinically, ESR, and CRP with a mean time to improvement of 7 to 8 weeks.⁹⁸ However, other retrospective studies have not confirmed this outcome,⁹⁹ and the results of prospective trials are awaited. Radiosynovectomy may be useful in the treatment of patients with monoarthritis or oligoarthritis. Rilonacept (IL-1 Trap), which is beneficial in the treatment of patients with chronic gouty arthritis, may be effective in patients with refractory CPP crystal-related arthritis.

Other treatment

Stronger analgesics such as opioids, NSAIDs, and coxibs may be required but carry an appreciable risk for side effects and drug interactions. Such drugs should be used with caution in the elderly. Patients should be clearly informed regarding optimal use, the requirement for drugs should be reviewed regularly, and "repeated" prescribing should be avoided.

Surgery

Patients with progressive or destructive large-joint arthropathy who require replacement appear to derive benefits equal to those with uncomplicated OA, without any increased risk for prosthetic failure.

191

Basic calcium phosphate crystal deposition disease

■ GERALDINE MCCARTHY

- Calcific periarthritis is characterized by periarticular deposits of calcific material (hydroxyapatite), which may also result in calcific tendinitis or bursitis.
- Intraarticular deposits of basic calcium phosphate (BCP) crystals may be found in joint fluid, as well as in synovium and articular cartilage.
- In calcific periarthritis, the shoulder is the main site affected, but deposits have been described near many other joints. The deposits are often inert and asymptomatic.
- Deposits can rupture and cause local acute, crystal-induced inflammation.
- Deposits may also be associated with local chronic pain and functional impairment.
- With intraarticular deposition, deposits are often inert and asymptomatic.
- Deposits occur with increased frequency in patients with osteoarthritis.
- BCP crystals can occasionally be shed into the joint and result in an acute synovitis resembling gout.
- BCP crystals are also found in abundance in the joints of older patients with large joint destructive arthropathies such as the Milwaukee shoulder syndrome.

HISTORY

Calcific periarthritis

Calcific scapulohumeral periarthritis was first described in 1870, and radiographic demonstration of periarticular shoulder calcifications was accomplished by 1907.¹ These calcifications were initially regarded as having arisen in the subdeltoid bursa but were subsequently demonstrated to occur chiefly in the supraspinatus tendon or the shoulder joint capsule. Thirty years later, renewed interest in periarthritis of the shoulder led to further descriptions of the phenomenon, as well as recognition of periarticular calcifications at other sites.² After another 30 years, it was recognized that the calcific material consisted of hydroxyapatite,³ and the pathophysiologic theory of primary tendon necrosis leading to secondary calcification followed.⁴ Subsequently, aggregates of basic calcium phosphate (BCP) crystals with their various crystalline structures and chemical compositions were further defined via ultrastructural and physical microanalysis techniques, including analytic electron microscopy, x-ray diffraction, and Fourier transform infrared (FTIR) spectroscopy.⁵ Included in the term BCP are crystals of partially carbonate-substituted hydroxyapatite, octacalcium phosphate, and rarely, tricalcium phosphate.

Intraarticular basic calcium phosphate crystal deposition

The earliest description of the pathoanatomic features of the consequences of intraarticular BCP crystal deposition appears to have been by Robert Adams in 1857, who called it “chronic rheumatic arthritis of the shoulder.”⁶ In his 1934 monograph, Codman reported the case of a 51-year-old woman who had what he called “subacromial space hygroma.” He described recurrent swelling of the shoulder, absent rotator cuff, cartilaginous bodies attached to synovial tissue, and severe destructive glenohumeral arthritis.⁷ These clinical descriptions were made without the benefit of modern diagnostic tests. The condition has subsequently been known by many different

names. In the French-language literature, the terms *les caries séniles hémorragique de l'épaule* and *l'arthropathie destructrice rapide de l'épaule* have been used, and in the English-language literature, terms such as *cuff tear arthropathy* appear. All early descriptions stress the involvement of older females and localization to the shoulder joint.⁷

The association of intraarticular deposits of BCP crystals with joint disease is much more recent. The presence of solid deposits of BCP crystals in the menisci of postmortem knees was noted in 1966,⁸ but it was not until 1976 that the first description of BCP crystals in degenerative joint diseases was recorded. Clumps of BCP crystals were discovered in the synovial fluid of patients with osteoarthritis (OA) via analytic electron microscopy,⁹ a finding that was confirmed by others.^{10,11} In 1981, McCarty's group described a similar large-joint destructive arthropathy, seen most commonly in the shoulder joints of elderly women, and called it *Milwaukee shoulder*. They noted the presence of large quantities of BCP crystals associated with collagenase in synovial fluid and hypothesized that the BCP crystals caused the associated joint destruction.¹² Subsequently, others noted that many large joints could be involved and terms such as *apatite-associated destructive arthritis* and *idiopathic destructive arthritis of the shoulder* were added to the list of names. BCP crystals were also described in the joint fluid of a few patients with acute synovitis and other forms of arthropathy.¹¹

EPIDEMIOLOGY

Calcific periarthritis

Few systematic studies of the incidence or prevalence of juxtaarticular deposits of BCP crystals have been done. These deposits are often asymptomatic and most commonly noted by chance on a radiograph obtained for other reasons (Fig. 191.1). In a unique, large study of office workers published in 1941, a 2.7% prevalence of shoulder deposits was noted in a North American, predominantly white population, 34% to 45% of which were associated with clinical problems.¹³ Females were affected more commonly than males, and the prevalence was highest in those between 31 and 40 years of age (19.5%). No comparable epidemiologic data have been reported subsequently, although a number of smaller pathologic or radiographic studies have documented the relatively high frequency of periarticular calcification. Calcific periarthritis has been reported in children as young as 3 years but appears to be relatively uncommon in the elderly. This suggests that many of the deposits seen in young adults must disappear spontaneously.

Articular calcification

The prevalence of intraarticular BCP crystal deposition has not been established because it has not been adequately studied. Apatite crystals are detected in up to 60% of synovial fluid samples from patients with knee joint OA.^{14,15} BCP crystals were found in approximately 50% of 53 preoperative OA knees.¹⁶ The prevalence in normal joints at different ages is not known. Milwaukee shoulder syndrome and the related BCP crystal-associated destructive arthropathies are uncommon, tend to occur in elderly individuals, and are of unknown prevalence.

CLINICAL FEATURES

Calcific periarthritis

Periarticular calcific deposits are often asymptomatic. However, they are also associated with a number of clinical syndromes (Table 191.1). The most

Fig. 191.1 Anteroposterior radiograph of the shoulder joint showing a large calcific deposit in the supraspinatus tendon. The deposit is dense, homogenous, and well defined, findings characteristic of inert periarticular deposits of calcific material.

TABLE 191.1

Clinical syndromes that can be associated with the deposition of basic calcium phosphate crystals in and around joints

Subcutaneous deposits (e.g., calcification of the hands in scleroderma)	Asymptomatic chance finding Acute and chronic inflammation Skin ulceration Secondary infection Pressing necrosis of surrounding tissues Mechanical interference with function
Periarticular deposits (e.g., calcification of the supraspinatus tendon)	Asymptomatic chance finding Acute calcific periarthritis Chronic periarticular pain and/or dysfunction
Intraarticular deposits (e.g., synovial and cartilage deposits in damaged joints)	Asymptomatic chance finding Acute synovitis Severe osteoarthritis Destructive arthropathies of older people

striking clinical finding is acute calcific periarthritis, which most commonly involves the shoulder but can occur in almost any joint. The episode may be preceded by mild trauma or overuse, but most cases have a spontaneous onset.

Patients report a sudden onset of severe pain, and within hours the affected part is usually swollen with redness and warmth of the overlying skin. There is extreme local tenderness and associated loss of function. At the shoulder the pain is most marked around the subacromial region and radiates down the outside of the arm. Glenohumeral movement is usually severely restricted. Severe pain may last for several days, but the symptoms then generally resolve slowly over a period of 2 to 3 weeks. A “frozen shoulder” may result.

Calcific periarthritis is thought to be caused by rupture of a calcific deposit into an adjacent soft tissue space or bursa along with initiation of an acute inflammatory reaction. In the shoulder the crystals may induce intense inflammation in the subacromial bursa (Fig. 191.2). Radiographically, calcium deposits appear dense with well-defined borders before an attack. With the onset of an attack, however, these calcific deposits appear fluffy with poorly defined margins. Ultimately, there is a reduction in the size of the deposit seen radiographically, and it may disappear completely.

Calcific deposits in periarticular tissues are also associated with chronic pain syndromes without a history of a previous acute episode. However, in the shoulder, because both chronic shoulder pain and calcification are common and because previous damage to tendons may predispose to calcification, it is difficult to define what contribution, if any, the deposits themselves make to the clinical findings. Moderate to severe pain is described, with varying degrees of tenderness and restriction of motion. Pain usually radiates to the insertion of the deltoid and sometimes beyond to the forearm. Lying on the affected shoulder is painful and may interfere with sleep. In some patients, recurrent acute attacks around the shoulder, separated by pain-free periods lasting months or years, are followed by the development

Fig. 191.2 Anteroposterior radiograph of the shoulder during an attack of severe acute calcific periarthritis. The deposit has become indistinct and ill defined as the crystals have been shed into the surrounding tissues. In this elderly patient, communication between the shoulder joint and the subacromial bursa led to a large effusion in the glenohumeral joint and a huge extension of the bursa into the upper part of the arm, as shown by the soft tissue swelling seen on the radiograph.

of chronic pain. Damage to the tendons and muscles of the rotator cuff may result and lead to total disruption of the cuff apparatus.

The shoulder is the most commonly affected site, followed by the hip, knee, elbow, wrist, and ankle joints. The joints of the feet and toes are less commonly involved (<1% of all reported cases), as are those of the hands and fingers.¹⁷ *Hydroxyapatite pseudopodagra* is a term used to describe acute calcific arthritis involving the first metatarsal phalangeal joint, usually in young women.¹⁸ Acute neck pain attributed to calcifications surrounding the odontoid process has been described and called the *crowned dens syndrome*. Calcifications appear to be composed of apatite, calcium pyrophosphate dihydrate (CPPD), or a combination of both.¹⁹

In some patients with multifocal deposits, symptoms develop at several sites, thus suggesting a more generalized condition rather than a chance localized process with resultant calcification. This manifestation can cause diagnostic confusion and may even mimic a seronegative polyarthritis. Several reports have described familial occurrences of calcific periarthritis.²⁰

Intraarticular basic calcium phosphate crystals

Our understanding of the exact relationship between intraarticular BCP crystals and joint pathology is incomplete, especially because special techniques are required to identify the crystals.²¹ Nonetheless, current data support the pathogenic role of BCP crystals in degeneration of articular tissue (Fig. 191.3). BCP crystals have been linked with several different diseases.

Acute synovitis

Acute attacks of arthritis associated with intraarticular BCP crystals in relatively young individuals have been described in the knee, as well as at other sites. The pain, swelling, and erythema resembled gout.²² These attacks appear to be rare, and the diagnosis is difficult to establish. Occasionally, crystals from a periarticular deposit can rupture into the joint itself and cause acute synovitis. This can occur in some older individuals who have a direct communication between the subacromial bursa and the glenohumeral joint.

Chronic monoarthritis, with or without erosions

A chronic, sometimes erosive monoarthritis has been linked with intraarticular BCP crystals. BCP crystals have been particularly implicated in finger joint arthropathies, including erosive or inflammatory forms of OA.²³ However, this phenomenon appears to be rare, and a direct contribution of BCP crystals to the observed pathology remains to be established.

SCHEMATIC REPRESENTATION OF THE POSSIBLE ASSOCIATIONS BETWEEN BCP CRYSTALS AND ARTHRITIS

Fig. 191.3 BCP, basic calcium phosphate; MMP, matrix metalloproteinase; PG, prostaglandin.

Osteoarthritis

Co-occurrence of BCP crystals and OA is well established. Ample data support the role of BCP crystals in cartilage degeneration because their presence correlates strongly with the severity of radiographic OA²⁴ and larger joint effusions are seen in affected knee joints than in OA knees without crystals.²⁵ Although the basis of the cartilage damage by BCP crystals has been the subject of numerous investigations, there are ongoing controversies concerning the relationship between calcium-containing crystals and OA and whether the crystals cause cartilage damage or are present as a result of joint damage.

Large-joint destructive arthropathies

A distinctive type of destructive arthropathy has been described in elderly individuals that is associated with rotator cuff defects and numerous aggregates of BCP crystals in the fluid of affected joints and is called Milwaukee shoulder.¹²

The clinical picture is characteristic (Fig. 191.4a). Patients are nearly always 70 years or older, and approximately 90% are females. They usually have a history (months or years) of increasing pain, swelling, and loss of function of the affected joint, typically the shoulder. The dominant side is usually involved initially, although 60% have bilateral involvement.²⁶ The pain may be mild but is typically most apparent at night and with use of the joint. Examination shows extensive damage to periarticular soft tissues, as well as to cartilage and subchondral bone on both sides of the joint. Active range of motion is reduced in all affected joints, sometimes associated with pronounced joint instability. Crepitation and pain may be noted, especially when the humerus is grated passively against the glenoid. In general, the rotator cuff is completely destroyed. Joint effusion is typically present and may be massive and extend into the subdeltoid region. Aspiration of affected shoulder joints routinely yields 3 to 160 mL of synovial fluid that is frequently blood tinged and has a low, predominantly mononuclear cell count (Fig. 191.4b). Rupture of the effusion can lead to massive extravasation of blood and synovial fluid into the surrounding tissue. Although the shoulder predominates, the knee, hip, elbow, and other joints may be involved.²⁷

The natural history of the condition is unclear, but many cases seem to stabilize after a year or two, with reduction of symptoms, joint effusions, and no further radiographic changes.

Additional clinical manifestations

A number of secondary forms of BCP crystal-associated arthropathy have been described. BCP crystal deposits have been reported in the joints and periarticular tissue of patients with renal failure, mostly when undergoing dialysis. Intraarticular injection of triamcinolone hexacetonide has been associated with the formation of periarticular calcifications along the injection tract, which may become apparent months after the injection. Such calcification may be gradually resorbed over a period of months to years. Occasionally, severe neurologic damage has been followed by heterotopic ossification in periarticular tissues that may mimic arthritis.

BCP deposition is also associated with connective tissue diseases, particularly scleroderma and dermatomyositis. Following dermatomyositis in childhood, massive sheets of fascial calcification can occur. In scleroderma, the deposits are usually subcutaneous. They are associated with the CREST

Fig. 191.4 Basic calcium phosphate crystal-associated destructive arthritis (Milwaukee shoulder syndrome). This elderly patient has visible swelling in both shoulders (a). Aspiration revealed a large amount of blood-stained fluid (b) that contained numerous particles of basic calcium phosphate.

syndrome (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia), but some patients have extensive calcification with little in the way of other features of the disease (calcinosis cutis) (Fig. 191.5). Occasionally, the hand calcification occurs on its own.

Tumoral calcinosis is a rare condition characterized by the progressive deposition of calcified masses in cutaneous and subcutaneous tissue; it is typically associated with chronic renal failure and hyperparathyroidism. Familial tumoral calcinosis is a heritable disorder typified by hyperphosphatemia, normal or elevated serum 1,25-dihydroxyvitamin D, and often severe ectopic calcifications. Mutations in the genes for both fibroblast growth factor-23 and GALNT3, which encodes a glycosyltransferase responsible for initiating mucin-type O-glycosylation, have been found in familial tumoral calcinosis. Finally, calciphylaxis is a dreaded complication of renal failure characterized by nodular subcutaneous calcification and painful tissue necrosis that often leads to ulceration, secondary infection, and high mortality rates.

INVESTIGATIONS

Imaging

A plain radiograph is the easiest method with which to detect and describe the calcific material of calcific periarthritis (Fig. 191.6). Anteroposterior and lateral radiographs are generally sufficient, but special views, with internal or external rotation of the shoulder, may be necessary to visualize retro-humeral deposits. The deposits are usually visualized in the rotator cuff, particularly the supraspinatus tendon a few centimeters from its insertion, but may also be seen in the subacromial bursa. Various appearances have been described with size varying from a few millimeters to several centimeters across. Other imaging investigations are rarely helpful in calcific periarthritis, although arthrography can be used to confirm cuff rupture and

Fig. 191.5 Anteroposterior radiograph of the hands of a patient with severe subcutaneous calcification associated with mild scleroderma.

Fig. 191.6 Anteroposterior radiograph of the shoulder joint showing a small periarticular calcific deposit. Other views may be necessary to identify small deposits and the site of deposition.

techniques such as computed tomography or magnetic resonance imaging may help demonstrate small deposits or other changes in the tissues around the lesion. During acute attacks of peri-arthritis the deposits may change and disappear, only to reappear again subsequently.

Calcification around joints is sometimes mistaken for ossification, although the presence of trabeculae in the latter should allow differentiation. The only other differential diagnosis on the images is the very rare formation of periarticular deposits of CPPD crystals. They occasionally occur in peri-articular tendons, but as in joints, the deposits usually appear as linear rather than nummular shadows.

Intraarticular BCP deposits are rarely visible with any of the conventional imaging procedures. Occasionally, articular calcifications of a nummular sort are seen, in contrast to the linear deposits of chondrocalcinosis as a result of CPPD crystals. However, pathologic studies indicate that individual aggregates of crystals in cartilage synovium or synovial fluid are generally tiny and well below the size that gives any chance of their being visible on a radiograph.

Radiographs in patients with Milwaukee shoulder syndrome are striking (Fig. 191.7) and show upward subluxation of the humeral head or arthrographic evidence of rotator cuff defects in the majority of patients. Other

Fig. 191.7 Anteroposterior radiographs of a shoulder joint affected by basic calcium phosphate crystal-associated destructive arthritis (Milwaukee shoulder syndrome). Extensive destruction of periarticular tissues, including the rotator cuff, has led to instability of the shoulder. The upward subluxation (a) of the humerus can be overcome by traction on the shoulder (b). Note the extensive atrophic destruction and loss of bone in both the acromion and the glenohumeral joint.

Fig. 191.8 Axial T2-weighted magnetic resonance image of a shoulder joint affected by basic calcium phosphate crystal-associated destructive arthritis (Milwaukee shoulder). There is advanced glenohumeral joint degeneration with loss of articular cartilage, truncation of the anterior and posterior labrum, narrowing of the joint space, osteophyte formation, muscle atrophy, and joint effusion.

findings may include cystic degeneration of the humeral tuberosities, erosions of cortical bone at the site of insertion of the rotator cuff, degenerative changes in the humeral head or glenoid of the scapula (or both), degenerative changes in the acromioclavicular joint, and calcification of the tendinous rotator cuff. Pseudarthrosis formation between the humeral head and the acromion and clavicle is common.

Magnetic resonance imaging can be used to further define the anatomic changes associated with Milwaukee shoulder syndrome, including loss of cartilage, periarticular bone marrow edema, rupture of the rotator cuff, synovial hypertrophy, and joint effusion (Fig. 191.8).

Biochemical

Apatite deposition usually occurs in the absence of any detectable metabolic abnormality. However, if multiple deposits are detected or if the deposits are unusually large or in unusual sites, calcium and phosphate levels, as well as renal function, should be checked. High serum phosphate levels seem

Fig. 191.9 Alizarin red S stain of a basic calcium phosphate particle isolated from the synovial fluid of a patient with osteoarthritis.

more likely to predispose to deposition than do abnormalities in calcium alone.

Synovial or bursal fluid

In acute calcific periarthritis it is sometimes possible to aspirate a mixture of calcium deposits and inflammatory matter from the bursa or periarticular tissue. It may look like toothpaste or be a creamy fluid, obviously full of “chalk.” In cases of intraarticular BCP crystal deposition, the synovial fluid findings vary. Usually, the fluids that contain BCP crystals have a low cell count, are viscous, and are much the same as fluids from any patient with OA. In the destructive arthropathies of the elderly there is frequent blood staining of the fluid. In addition, numerous cartilage fragments and other debris may be present, although the cell count is low.

Identification and characterization of basic calcium phosphate crystals

Study of BCP crystal-associated arthritis has been relatively difficult because of the lack of a simple, easily accessible, reliable diagnostic test.²¹ BCP crystals are not birefringent. Therefore, polarized light microscopy is not useful for detection of them because individual BCP crystals, which are typically needle shaped and less than 0.1 μm long, cannot be resolved by light microscopy and are randomly oriented in the much larger aggregates (2 to 19 μm) in which they are usually found. Plain and polarized light microscopy of samples containing apatite may show globular clumps of crystals, which can look like shiny coins, but the usual appearance of these crystals is nondescript.

Calcium stains such as alizarin red S have been used by some investigators to identify BCP crystals.²⁸ Clumps of crystals show up with a “halo” of stain (Fig. 191.9). Alizarin red S is highly sensitive, but frequent false-positive results suggest that it lacks sufficient specificity to qualify for routine identification of BCP crystals without some other type of confirmatory testing.

A semiquantitative binding assay for BCP crystals that uses [¹⁴C] ethane-1-hydroxy-1,1-diphosphonate (EHDP) has been described.¹⁰ Diphosphonates are analogues of inorganic pyrophosphate that adsorb to the surface of BCP crystals but not to monosodium urate, CPPD, cartilage fragments, or any other known particulates in joint fluid. This method is performed on a synovial fluid pellet resuspended in phosphate-buffered saline, and the results are expressed as micrograms per milliliter of hydroxyapatite standard. The limit of sensitivity is approximately 2 $\mu\text{g/mL}$ standard hydroxyapatite.

Electron microscopy can be used to visualize the crystals in synovial fluid pellets, and if elemental analysis or electron diffraction is possible, their identity can be confirmed (Fig. 191.10). If sufficient material is available, (e.g., from surgical specimens), other analytic techniques such as x-ray powder diffraction or FTIR spectroscopy can be used to identify the material. The latter has shown that BCP crystal deposits consist of mixtures of hydroxyapatite, octacalcium phosphate, and rarely tricalcium phosphate crystals. Combinations of both BCP and CPPD crystals are not infrequent.

Fig. 191.10 High-magnification transmission electron micrograph of basic calcium phosphate crystals. The crystal lattice structure and morphology of the crystals are apparent.

Atomic force microscopy has been applied to the identification of synovial fluid microcrystals and is capable of achieving subnanometer resolution of crystal surface topology and measurement of lattice unit cell dimensions.²¹

More novel methods of identifying BCP crystals from synovial fluid include isolation using bisphosphonate-modified superparamagnetic beads and identification via oxytetracycline staining, which fluoresces under ultraviolet light. Synchrotron FTIR spectroscopy can accurately distinguish between CPPD and BCP crystals.²¹

The ability to identify apatite is less crucial than the identification of monosodium urate or CPPD crystals from a clinical perspective because no drug has yet been identified that specifically inhibits the pathologic effects of BCP crystals *in vivo*.

DIFFERENTIAL DIAGNOSIS

Acute calcific periarthritis

The differential diagnosis of acute calcific periarthritis should include gout, pseudogout, and sepsis. However, the distribution of the lesions and acute onset are often characteristic. Radiographs showing the evolution of the calcific deposit are virtually pathognomonic. The diagnosis can be confirmed if material can be aspirated from the area.

Chronic periarticular syndromes

The usual features are those of tendinitis, and the only way of implicating crystal deposition in the diagnosis is through visualization of the deposit on a radiograph. Other causes of tendinitis such as trauma, impingement, and inflammatory arthritis are possible differential diagnoses.

Acute and chronic arthritis

Acute inflammatory arthritis that may mimic gout, pseudogout, or other systemic inflammatory rheumatic diseases has been attributed to BCP crystals.^{9,22} BCP crystals are often detected in OA joints and appear to promote the degenerative process.^{24,25} Erosive arthritis with recurrent episodes of pain and swelling involving the wrists and finger joints has been associated with BCP crystal deposition.²³

Destructive arthropathies of the elderly

The main differential diagnoses include neuropathic or Charcot joints, chronic sepsis, advanced rheumatoid disease, osteonecrosis, and CPPD deposition disease. Radiographic involvement of both sides of the joint helps differentiate this condition from osteonecrosis. The absence of any neurologic deficit distinguishes it from Charcot arthropathy. Synovial fluid examination and culture will aid in differentiation from CPPD deposition disease and sepsis.

STRUCTURE AND FUNCTION

Nature of the crystals

Hydroxyapatite is a form of calcium phosphate represented by the formula $\text{Ca}_5(\text{PO}_4)_3\text{OH}\cdot 2\text{H}_2\text{O}$ and is usually found in partially substituted carbonated form. In periarticular calcific deposits, light microscopy generally shows multifocal aggregates of crystals separated by fibrocollagenous tissue. On transmission electron microscopy the deposits appear as rounded aggregates with isolated crystals in a matrix of fragmented collagen fibers (Fig. 191.11). On scanning electron microscopy they look like rocky bulks embedded in mortar (Fig. 191.12). The crystals are heterogeneous both within the sample and in different patients. Typically, they include compounds of varying crystallinity ranging from amorphous BCP to well-structured stable elements, similar to those of bone and teeth, but with a larger crystal size than most of the crystals seen in bone. In bone, poorly crystalline, partially carbonated crystals of hydroxyapatite, each about 500 Å in length, are the main mineral phase. The crystals of periarticular deposits are often more carbonated than bone crystals are, and high-resolution electron microscopy suggests that some of them are coated with electron-dense material.

In synovial fluid samples, mixed populations of BCP crystals have been reported, including partially carbonate-substituted hydroxyapatite, octacalcium phosphate ($\text{Ca}_8\text{H}_2(\text{PO}_4)_6\cdot 5\text{H}_2\text{O}$), and rarely, tricalcium phosphate ($\text{Ca}_3(\text{PO}_4)_2$). They frequently coexist with CPPD crystals and are associated with particulate collagens.²⁹ One report suggested that the crystals extracted from synovial fluid were more like those found in periarticular calcific deposits than in bone crystals, thus suggesting that they were derived from newly formed deposits and not from subchondral bone.³⁰

Fig. 191.11 Transmission electron micrograph of basic calcium phosphate crystals from a tendon deposit. Clumps of crystals, dense globular structures of various size, and isolated crystals can be seen.

Fig. 191.12 Scanning electron micrograph of a calcific deposit isolated from a tendon.

Another form of BCP, magnesium whitlockite, has been identified in the superficial region of articular cartilage. Some studies suggest that it may be a frequent finding in normal and diseased hyaline cartilage.³¹ This observation, coupled with the identification of some hydroxyapatite crystals in normal cartilage, has led to speculation that some BCP minerals may have a physiologic rather than a pathologic role in cartilage homeostasis. However, whitlockite crystals elicit biologic cellular responses, including mitogenesis and matrix metalloproteinase production *in vitro*, that suggest potential pathogenicity in arthritis.³²

ETIOLOGY

The mechanism of periarticular calcification is largely unknown, although periarticular intratendinous deposits have been thought to be due to ectopic calcification of damaged tendons. In most patients, no obvious local, metabolic, or genetic cause of the calcification is found. The frequent occurrence of bilateral and multifocal deposits suggests the operation of a generalized predisposition, as well as local factors. This is supported by the fact that the sites of deposition in sporadic cases of calcific periarthritis are the same as those associated with a known systemic predisposition such as diabetes mellitus, hyperthyroidism, or parathyroid disorders. The classic description of a relationship between repetitive shoulder use and the formation of calcific deposits has not been established. There is no known relationship with any HLA specificity or other genetic marker despite the known occurrence of familial cases, some with extensive pedigrees.

PATHOGENESIS

Calcific periarthritis

Pathologic assessments have shown that the calcific deposits are located in tendons, peritendinous tissues, bursae, or ligaments. Original studies suggested that “dystrophic” tendon calcification occurs as a consequence of local trauma, ischemia, and necrosis of tendons. Calcific periarthritis frequently localizes to the supraspinatus tendon in a poorly vascularized area of the tendon sheath known as the “critical zone,” a few millimeters from the bone insertion. Similarly, calcification in other tendons seems to occur preferentially in hypovascular segments, which suggests local necrosis followed by ectopic calcification.

Some evidence has indicated that calcifying tendinitis is an active, cell-mediated process in which local vascular and mechanical changes result in focal transformation of tendinous tissue into fibrocartilaginous material containing chondrocytes. This is followed by local deposition of hydroxyapatite crystals within extracellular matrix vesicle-like structures derived from these chondrocytes.³³

Acute calcific periarthritis appears to be induced by rupture of the deposit and shedding of the crystals into more cellular vascular areas. BCP crystals have been shown to be intrinsically phlogistic. They are phagocytosed *in vitro*, which results in the release of inflammatory mediators.³⁴ Similarly, *in vivo* models of inflammation show a brisk inflammatory reaction to apatite, and injection into the tissues of human volunteers results in an inflammatory response.³⁵ Phagocytosis may be one of the main ways in which the crystals are removed.

Evidence indicates that coating of the crystals, which have highly adsorptive surfaces, can either stimulate or suppress the inflammatory response, depending on the nature of the proteins that attach to the crystals.³⁶ Immunoglobulins, for example, may activate inflammatory responses, whereas coating of apolipoproteins on the crystal surfaces will suppress such responses.

Tumoral calcinosis

Light microscopic and immunohistochemical studies have indicated that the calcifying process in tumoral calcinosis and calciphylaxis involves histiocytes and osteoclast-like giant cells of histiocytic origin. Hydroxyapatite crystal formation and calcification appeared to develop predominantly from intracytoplasmic membrane-bound vesicles and also from mitochondria.

Relationship with osteoarthritis and destructive arthropathies

Crystals of BCP are frequently found in OA cartilage, synovium, and synovial fluid. Evidence suggests that human osteoarticular cartilage contains matrix vesicles that are capable of progressive mineralization and can

Fig. 191.13 Bones from a patient with advanced basic calcium phosphate crystal-associated destructive arthritis. The humerus (a) shows the extensive bony attrition characteristic of this condition. The tibial condyles (b) show the characteristic destruction of the lateral tibiofemoral joint, with extensive loss of subchondral bone. L, lateral; M, medial.

generate either BCP or CPPD crystals *in vitro*.³⁷ However, more than one source of formation is likely. For example, the ANK gene product, a cell membrane protein, regulates extracellular inorganic pyrophosphate (ePPi). ePPi is an important inhibitor of nucleation and growth of BCP crystals. ANK-mediated control of ePPi levels is a possible mechanism of regulation of tissue calcification.³⁸ In support of this concept, the roles of the ANK gene and the *TNAP* gene, the product of which also regulates ePPi, have been investigated in patients with cuff tear arthropathy. Variant genotypes for both were observed more frequently in cases than in controls.³⁹

The degree of damage that can occur in apatite-associated destructive arthropathies is marked (Fig. 191.13), but the basis of the cartilage damage by calcium-containing crystals is still somewhat speculative. Theoretically, crystals in cartilage may directly injure chondrocytes. However, in pathologic specimens, crystals are rarely seen in immediate contact with chondrocytes and even less frequently found engulfed by chondrocytes.

It is more likely that cartilage damage ultimately results from effects of the crystals on synovial lining. *In vitro* properties of BCP crystals that emphasize their pathogenic potential have been observed.⁴⁰ BCP crystals induce cellular mitogenesis, a characteristic that presumably leads to synovial proliferation, characteristic of both Milwaukee shoulder syndrome and apatite-associated OA.⁴¹ They can induce the secretion of proteolytic enzymes that lead to the degradation of intraarticular collagenous structures.⁴⁰ Similarly, BCP crystals induce cyclooxygenase-1 (COX-1) and COX-2, followed by increased prostaglandin E₂, and induce proinflammatory cytokines and danger-associated molecules via activation of Syk and phosphatidylinositol 3'-kinase.^{35,42,43} Finally, recent evidence supports a role of the NLRP3 inflammasome in the pathogenesis of BCP crystal-associated arthropathies.⁴⁴

Despite the association of BCP crystals with OA and joint destruction and the biologic effects noted *in vitro*, the specific role of the crystals in joint degeneration is controversial. Some hypothesize that the BCP crystal aggregates found in association with destructive arthropathies actually originate from damaged subchondral bone and are merely an epiphenomenon. More studies will be necessary to further differentiate between crystals as a cause of cartilage damage and crystals as a result of cartilage damage. Improved understanding of the biologic effects of BCP crystals is essential for ultimate prevention or reversal of the consequences of deposition.

MANAGEMENT

Calcific periartthritis

Asymptomatic deposits require no treatment. Acute attacks of calcific periartthritis have been treated successfully with immobilization and a variety of nonsteroidal antiinflammatory drugs (NSAIDs) or colchicine. Most patients have markedly reduced symptoms within 5 days and virtually complete resolution within 1 to 3 weeks. Untreated attacks may last several weeks. Needle aspiration of the pasty calcific deposits with or without irrigation may be helpful. The use of corticosteroids is controversial; local corticosteroid injections will help resolve the acute attacks but may possibly make further calcification and recurrent attacks more likely.

For patients with chronic periarticular syndromes, treatment is in general much the same as it would be regardless of whether deposits are present. In chronic calcific tendinitis, ultrasound treatment helps resolve calcifications and is associated with short-term clinical improvement.⁴⁵ Treatment with disodium ethylenediaminetetraacetic acid can result in significant improvement in shoulder function and pain levels and the disappearance of calcifications with no adverse effects.⁴⁶

If the problem persists and large calcific deposits are present, other treatments can be considered. Local corticosteroid therapy should be used with caution because of the risk of disrupting the deposit or seeding further calcification. Needle aspiration is usually difficult in chronic cases, but arthroscopic or surgical removal may provide permanent symptomatic relief in refractory cases.

Tumoral calcinosis

Recently, successful treatment of both tumoral calcinosis and calciphylaxis with intravenous sodium thiosulfate has been reported.⁴⁷ The beneficial effect of sodium thiosulfate has been ascribed to the extremely high solubility of calcium thiosulfate salts, which results in inhibition of precipitation of calcium salts and dissolution of calcium deposits with subsequent mobilization of tumorlike masses. Whether this is in fact the mechanism of action is unknown, as is the optimal duration of treatment.

Articular basic calcium phosphate crystals

Currently, patients with OA complicated by BCP crystal deposition should be treated in the same manner as though they had simple OA because no specific treatment has been identified or tested. It is hoped that ongoing research endeavors will ultimately lead to the development of more specific treatment of apatite deposition.

At the time of diagnosis of BCP crystal-associated destructive arthropathies such as Milwaukee shoulder syndrome, advanced destructive changes are usually present and may even be asymptomatic. Treatment of symptomatic disease is generally unsatisfactory. A conservative approach that includes analgesics and NSAIDs, repeated shoulder aspirations, and decreased joint

use has sometimes controlled the symptoms satisfactorily. In theory, nonselective COX inhibition would be more effective because BCP crystals induce both COX-1 and COX-2. Surgical therapy is sometimes successful in relieving pain and restoring function but may be difficult because of the extent of damage to the joint and periarticular tissues. Surgical procedures include arthroscopic lavage or débridement (or both), humeral tuberopecty arthrodesis, arthroplasty, and hemiarthroplasty.⁷ Some patients have responded to closed-needle tidal-joint irrigation followed by the injection of methylprednisolone acetate (40 mg) and tranexamic acid (0.5 g).⁴⁸ Other pain-relieving measures such as suprascapular nerve blocks for shoulder disease or transcutaneous nerve stimulation have been used with some success. The pain may subside with time alone.

Other crystal-related arthropathies

■ LAN X. CHEN ■ H. RALPH SCHUMACHER, JR.

- The clinical significance of non-monosodium urate monohydrate joint crystals, calcium pyrophosphate dihydrate crystals, and hydroxyapatite crystals varies widely, depending on the crystal.
- Oxalate and depot corticosteroid crystals have established pathogenic potential.
- Other crystalline material with possible pathogenic implications includes liquid lipid crystals, cholesterol, other lipids, hematoidin, immunoglobulins, Charcot-Leyden crystals, and foreign bodies.
- Crystal-like artifacts are potential sources of confusion.

HISTORY

Identification of the infrequently found joint, bursa, or subcutaneous crystals remains an evolving topic. This has been stimulated largely by the technique of polarized light microscopy introduced by Hollander and McCarty in the early 1960s and by the expanded use of microscopic examination of joint fluids as part of the routine diagnostic evaluation of arthritis. Oxalate crystals in joint fluids were first reported in 1982,¹ and depot corticosteroids have, since their introduction in 1951, been known to be able to cause inflammation occasionally.²

In this chapter the suggestive clinical features and appropriate investigations are described for these and several less common crystals.

Oxalate crystals

Oxalate crystals are found less often in synovial fluid than monosodium urate, calcium pyrophosphate dihydrate (CPPD), and apatite crystals are, even though they can be associated with acute or chronic arthritis. Oxalate crystal deposition disease is seen in patients with primary familial hyperoxaluria types 1 and 2 (PH1 and PH2) and in patients with end-stage renal disease (ESRD), especially in those maintained long-term on dialysis.³ In addition to deposition in joints and bones, oxalate crystal deposits are found mainly in the kidneys, skin, and vessels. Clinical and radiographic features include calcium oxalate osteopathy, acute and chronic arthropathy with chondrocalcinosis, synovial calcification, milium skin calcium oxalate deposits, and vascular calcifications that for some unknown reasons affect mainly the hands and feet.³

Oxalate is present in several edible plants and fruit. The gut does not absorb much oxalate from the diet because most will be metabolized by the flora or leave the body in stool. In patients with inflammatory bowel disease such as Crohn and ulcerative colitis, much dietary oxalate is absorbed with a resulting increase in serum oxalate levels.³ Variation in absorption of dietary oxalate can range from as little as 1% to 2% to as high as 50%.

Oxalate can be produced endogenously, and production can be increased as a result of enzyme imbalance because of genetic variation or differences in lifestyle with varying intake of vitamin B₆, magnesium, or thiamine. Increases in oxalate generation can also be a consequence of high doses of vitamin C or consumption of high levels of fructose.³

PH1 is a rare autosomal recessive metabolic disorder that results in the overproduction of plasma oxalate.⁴ Although the enzymatic defect resides in hepatocyte peroxisomes, uncontrolled levels of oxalate result in calcium oxalate deposition in multiple organs. Because the primary route of elimination of oxalate is renal excretion, high levels are found in urine. Patients typically have recurrent nephrolithiasis and nephrocalcinosis. If not

diagnosed early, ESRD and systemic calcium oxalate deposition can occur. Once ESRD develops, intensive dialysis therapy is unable to keep pace with the high oxalate production, and the preferred therapeutic intervention is combined kidney-liver transplantation. The diagnosis of PH1 must be considered in the differential diagnosis of patients with ESRD and a history of recurrent nephrolithiasis. Genomic DNA studies have identified the genetic defects leading to PH1 and PH2, thereby allowing precise early diagnosis.³

Oxalate deposition may complicate amyloid-induced renal failure in patients with rheumatoid arthritis.⁵ Total leukocyte and differential counts in synovial fluid vary but are generally less than 2000/mm³. Inflammatory reactions in tissue may be absent, or a granulomatous response around the crystals may be noted. Oxalates may also be found in intervertebral disks and contribute to disk destruction in dialysis patients.⁶ Because oxalosis is also generalized in many of these patients, crystal deposition can occur at other sites as well, including bone marrow.⁷ Oxalosis can thus cause vascular insufficiency with gangrene.⁸ Although oxalosis can occur as a result of small bowel resection or inflammatory bowel disease, oxalate-induced arthritis has not yet been reported as a complication of these causes.

Definitive diagnosis is achieved by identification of crystals in joint fluid or by biopsy of joints, bones, or other tissues. Synovial fluid crystals can be pleomorphic but characteristically include at least some with bipyramidal or envelope-like shapes (Fig. 192.1), a distinctive feature that helps in the differential diagnosis. Sizes range from 5 to 30 μ m. Most crystals are strongly birefringent, although some of the smaller rodlike ones can have positive elongation that could cause confusion with CPPD. Most also stain brightly with calcium stains such as alizarin red S, which might cause further confusion with the various apatite-like crystals or CPPD. Under electron microscopy, oxalates are electron dense and foamy and thus are indistinguishable from CPPD without elemental analysis, which shows that the oxalates contain calcium but no phosphorus. X-ray or electron diffraction, infrared spectroscopy with Fourier transformation, or Raman spectroscopy can be helpful in making the diagnosis when available and used by experienced operators.

Radiographs of joints can show calcifications. The opacification of articular structures seen with oxalates can be found in cartilage or soft tissue and can mimic either CPPD or apatite-associated diseases. Some patients with articular oxalates will have no calcification visible on radiographs. Oxalate-infiltrated bones show various patterns, including sclerosis and demineralization.

Depot corticosteroid crystals

The obvious clinical clue to this phenomenon is known or suspected recent intraarticular or bursal injection.^{9,10} If an inflammatory reaction occurs, it is most frequent during the first 8 hours after injection. Such reaction tends to help distinguish this phenomenon from an infection, which generally develops considerably more slowly.

Depot corticosteroid crystal-induced inflammation appears to be more common with triamcinolone hexacetonide than with other preparations. The former preparation is also less soluble, which may increase the chance of inducing acute inflammation. Inflammatory responses have been shown to vary among the different depot corticosteroids after injection into rat air pouches.¹¹ The inflammation may be transient because of corticosteroid suppression as it dissolves in the joint. Even joints in patients with osteoarthritis that are dramatically improved promptly after corticosteroid injection may transiently show depot corticosteroid crystal phagocytosis and mildly increased leukocyte counts in synovial fluid.¹² The diagnosis can be supported by aspiration and identification of pleomorphic crystals, which include irregular shapes, rods, and squares with intense positive or negative birefringence (Fig. 192.2). Phagocytosis of crystals by neutrophils and

Fig. 192.1 Oxalate crystals from synovial fluid seen with regular, unpolarized light. Note that some crystals have the characteristic bipyramidal shape ($\times 400$).

Fig. 192.2 Bright, irregular, depot corticosteroid crystals. Crystal morphology can vary widely with preparation, batch, and duration of storage (compensated polarized light, $\times 400$).

mononuclear cells can be observed.¹³ When acute inflammation develops after an injection, it may be necessary to perform a Gram stain and obtain material for culture to exclude infection. Radiographs are not helpful. Depot corticosteroids can also be artifacts as a result of contamination of specimens during handling if a corticosteroid is injected after arthrocentesis.

Lipid crystals

Lipid crystals may be pathogenic or potentially confusing factors when present in joint effusions.

Cholesterol crystals

Cholesterol crystals (Fig. 192.3) may be a complication of joint effusions resulting from rheumatoid arthritis (Fig. 192.4). Other less common causes include osteoarthritis, and crystals are also found in sites such as the olecranon bursae. Cholesterol crystals are most often seen as broad plates with a notched corner. Needle-shaped crystals with negative elongation (which are not monosodium urate crystals) may also be seen in cholesterol-laden fluid.¹⁴ Synovial fluid may have a glossy golden appearance. Cholesterol crystals may develop in rheumatoid nodules and gouty tophi and have been found in rheumatoid pericarditis.

There is some debate that although cholesterol crystals are often too large to undergo phagocytosis, they may contribute in some way to perpetuation of inflammation. Evidence in support of this comes from studies of injection of cholesterol crystals subcutaneously to stimulate inflammation.¹⁵ Similarly, injection into guinea pig gallbladders caused increases in interleukin-1, myeloperoxidase, prostaglandin E_2 , and prostaglandin F in luminal fluid.¹⁶ Cholesterol-containing subcutaneous tophi or ganglion-like nodules have also been described,¹⁷ and the sites involved may be related to repeated local microtrauma.

Lipid liquid crystals

Lipid liquid crystals are caused by lipid states with the characteristics of both liquids and solids; they form layered arrays that appear as birefringent microspherules.¹⁸⁻²⁰ They form from phospholipids released from red blood cells or other cells. Trauma with hemarthrosis has preceded some but has not been evident in all cases, so other sources of these lipid spherules should be considered, such as other antecedent inflammatory exudation. When present in large number, lipid liquid crystals resembling Maltese crosses may undergo phagocytosis and be associated with acute joint symptoms. Most patients have monoarthritis. The knees are most frequently involved, but wrist involvement and even polyarthritis, with possibly similar mechanisms,

Fig. 192.3 Classic cholesterol plates with overlapping and some corner notching (compensated polarized light, $\times 400$).

Fig. 192.4 Red tender swelling at the first metatarsophalangeal joint in a patient with rheumatoid arthritis from which fluid with a large number of cholesterol crystals was aspirated.

Fig. 192.5 Positively birefringent Maltese cross-like lipid microspherules from the synovial fluid of a patient with otherwise unexplained acute arthritis (compensated polarized light, $\times 1000$).

have been reported. Synovial fluids have been inflammatory and contain 10,000 to 40,000 leukocytes/ mm^3 , with intracellular "Maltese crosses" identified in many samples. Polymorphonuclear leukocytes or macrophages are the predominant cells.

Lipid liquid crystals are readily identified under compensated polarized light as 2- to 20-mm Maltese cross-like spherules with the two blue parts of the cross lined up parallel to the axis of slow vibration of the compensator (positive elongation) (Fig. 192.5). Rare Maltese crosses are not clinically significant, but when they are frequent and intracellular, they should be considered as possible causes of the arthritis if no other explanation is

evident. Lipid liquid crystals need to be distinguished from starch derived from gloves, which has a more polygonal outline, and from rare urate microspherules, which have negative birefringence.

Other lipids

There is interest in whether lipid crystals can explain some of the arthritis and tenosynovitis reported to complicate type II and IV hyperlipoproteinemia. A case report describing incompletely characterized, brightly positively birefringent rodlike crystals in a tendon of a man with hypercholesterolemia and Achilles tendinitis is suggestive.²¹ Most hyperlipidemic patients do not have lipid crystals. Synovial xanthomatosis has been described with normal serum lipid levels.²² Synovial biopsy specimens can show infiltration with foam cells.

Nonbirefringent droplets composed largely of neutral lipids are common after trauma, with lymphatic obstruction, in pancreatic disease, and occasionally in type IV hyperlipoproteinemia. Fractures into joints can produce tomato soup–like bloody effusions with lipid droplets that will rise to the surface on centrifugation.²³ Chylous effusions secondary to lymphatic obstruction or trauma can be milky with chylomicrons.^{24,25} Needle-shaped crystals with negative elongation can precipitate in neutral lipid droplets, especially during storage, and can be a source of confusion with urates. Uricase digestion can be used to determine whether urate crystals are present, although this may be difficult to interpret if only rare urates are mixed with the lipid crystals. Crystalline lipids do not generally stain with fat stains as do neutral fat droplets.

Protein crystals

Data on protein crystals are limited, with most based on case reports. One interesting case report involved a patient who had chronic polyarthritis that appeared to be due to massive intraarticular crystalline precipitates of an IgG cryoprecipitable paraprotein.²⁶ This patient had an erosive arthritis with inflammatory synovial fluid (30,000 leukocytes/mm³, 90% polymorphonuclear neutrophilic leukocytes) and chronic inflammation in the synovium surrounding deposits of crystals. Another patient with multiple myeloma had polyarthritis with weakly birefringent rhomboid crystals that were not observed until the synovial fluid cooled.²⁷ Other patients with cryoglobulinemia may have arthritis without synovial fluid crystals. In vessels, crystallized cryoglobulin or myeloma proteins can cause vascular obliteration. Cryoglobulin crystals have been emphasized as a cause of both destructive arthritis and vasculopathy.²⁸ A mouse model of IgG3 cryocrystal globulinemia has been reported with deposits in kidneys.²⁹

Immunoglobulin crystals are pleomorphic and may be larger than 60 nm. However, they can also appear as smaller squares, hexagons, rhomboids, or rods and potentially be confused with known pathogenic crystals. Because they are proteins, they will stain with methylene blue (Fig. 192.6). Some crystals are negatively birefringent. Monoclonal antibodies can provide specific identification. Other protein crystals described in synovial fluid and other sites include Charcot-Leyden crystals,^{30–32} which are believed to be composed of lysophospholipase in eosinophil-laden fluid; hemoglobin; and hematoidin. Charcot-Leyden crystals have a characteristic spindle shape and are weakly birefringent with positive or negative elongation (Fig. 192.7). Hematoidin crystals (Fig. 192.8), derived from the breakdown of hemoglobin, are rhomboids very similar to CPPD, except for their golden color on regular light microscopy. Other golden debris and stellate arrays are rarely seen but have been identified as hematoidin at other sites.^{23,33,34} Their identification and possible modes of formation have been reviewed.^{33,34} Because hematoidin and Charcot-Leyden crystals can undergo phagocytosis, they may have phlogistic potential. Hemoglobin has also rarely been noted to crystallize out as rods in dried smears containing red cells.³³

Fig. 192.6 Myeloma protein crystals (compensated polarized light, ×100).

Crystalline and other potentially confusing foreign material

Foreign bodies can cause acute or recurrent arthritis that is usually monoarticular. These bodies may be crystalline or poorly crystalline. The penetrating injury may not be recalled. Most foreign bodies become embedded or sequestered in synovial tissue and consequently are not seen in synovial fluid. Thus, arthroscopy or arthrotomy may be required for diagnosis. There are a number of examples of foreign bodies with such effects. Plant thorns can be associated with dramatic packing of cells and cellulose that is accentuated with polarized light. Calcium carbonate from sea urchin spines is birefringent and irregular. Birefringent fiberglass fibrils or polyethylene and methacrylate wear particles in patients with joint replacements have also been described in joint fluid.³⁵ Silicone wear particles can produce granulomatous reactions in synovium in patients with failure of finger implants.³⁶ Wear particles from metallic prosthetic implants can be dark metal shards.³⁷ Any of these particles can undergo phagocytosis and be a cause of low-grade inflammation.^{38,39} Aluminum crystals have been reported in joints in patients with systemic aluminum toxicity. Most foreign bodies are not radiopaque, and magnetic resonance imaging may help identify some of them. Patients with the rare inflammatory reactions after hyaluronate G-F 20 injections may have shiny, nonbirefringent inclusions in synovial fluid cells.⁴⁰

INVESTIGATIONS AND DIFFERENTIAL DIAGNOSIS

Methods for investigation and differential diagnosis span the variety of techniques in use for the more commonly recognized crystal-associated syndromes. They can include regular and polarized light microscopy, electron microscopy, elemental analysis, x-ray or electron diffraction, Fourier transform infrared analysis, and atomic force microscopy. In addition, monoclonal antibodies can be used to stain immunoglobulin crystals, and the Fouchet stain can probably help identify hematoidin.²³ To exclude the more common diseases, uricase or pyrophosphatase digestion may be attempted. Artifacts seen on wet preparations with regular or polarized light have frequently been a source of diagnostic confusion (Box 192.1).⁴¹ Figures 192.9 to 192.12 illustrate some of the artifacts found.

ETIOLOGY AND PATHOGENESIS

As each new crystal of suspected pathogenic significance has been suggested, new techniques have been used by investigators to help establish

Fig. 192.7 Charcot-Leyden crystals (regular light microscopy, ×400).

Fig. 192.8 Golden rhomboid-shaped hematoidin crystal along with many monosodium urate crystals (regular light microscopy, ×400).

BOX 192.1 CRYSTAL-LIKE ARTIFACTS SEEN IN SYNOVIAL FLUID WET PREPARATIONS

Depot corticosteroid crystals
 Glass fragments
 Nail polish from sealed coverslip edges
 Wood fragments from sticks used in transport
 Starch from gloves
 Anticoagulant crystals—sodium oxalate, lithium, heparin
 Precipitates from storage—calcium phosphates, oxalates, hemoglobin, hematoidin, lipids, unidentified material
 Dust
 Lens paper fibrils
 Polyester from yellow serum separator tubes

Fig. 192.9 Slivers of glass from coverslips can be needle shaped and mimic monosodium urate crystals, even to the point of having negative elongation in compensated polarized light ($\times 400$).

Fig. 192.10 Starch from gloves produces Maltese cross-like particles that are more angular than liquid lipid crystals. Calcium phosphates stained here with alizarin red S are also present in some powders (compensated polarized light, $\times 400$).

their identity and to test their inflammatory potential. Crystals can be tested for inflammatory properties by intraarticular injection, injection into the pleural space, or injection into air pouches on the dorsum of the rat, which produces a synovial-like space.⁴² *In vitro* incubation with various cells and chemotactic assays are also used. Some crystals may not produce acute, readily detectable inflammation but may interact with chronic inflammatory cells and still have a long-term impact. Studies may well be worth extending to better define any important roles of crystals such as cholesterol, lipid liquid crystals, and hematoidin and also to investigate prosthetic wear particles and polymethyl methacrylate cement, which may

Fig. 192.11 Negatively birefringent needles precipitate in synovial fat droplets during storage. When they are released into joint fluid, they can mimic monosodium urate crystals (polarized light, $\times 400$).

Fig. 192.12 As fluid dries, birefringent salts precipitate (compensated polarized light, $\times 100$).

produce inflammation in ways similar to crystals.^{39,42} Injection of polymethyl methacrylate cement into rat air pouches⁴² does produce inflammation. Cholesterol crystals can activate the inflammasome and complement,^{43,44} thus suggesting a process that might be involved in atherosclerotic plaque, as well as in joints or bursae. Surface charge, binding properties, and activation of the inflammasome can also be studied with other crystal or crystal-like particles. An organic matrix is associated with oxalate stones, and proteins may well also bind to oxalates in joints.

The reasons why only very few individuals have deposits of the crystals discussed earlier despite apparent similar risks are also potential areas for investigation. Some investigations suggest direct mechanisms for crystal production. Thus, lipid liquid crystals were shown to result from hemorrhage after blood was injected into joints and Maltese cross-like particles developed.⁴⁵

MANAGEMENT

Treatment of inflammatory episodes related to these less common crystals has not been studied systematically. When the clinical situation permits, nonsteroidal antiinflammatory drugs are generally used for oxalate-associated inflammation or to temporarily help with depot corticosteroid-induced bouts. Rarely, depot corticosteroid crystals have to be aspirated from unusually prolonged iatrogenic corticosteroid crystal-induced inflammation. Measures to deplete the crystals discussed here are not known. Oxalate accumulation in hemodialysis patients may be slowed by avoiding the use of vitamin C, which is metabolized to oxalate. Cryoglobulins can be decreased by treating the underlying disease, and one patient's arthritis improved with oral and intraarticular corticosteroids.²⁷ In a patient with Waldenström cryoglobulinemic vasculitis, rituximab initially increased cryoglobulin levels but then led to a response.⁴⁶ Foreign bodies, of course, are best managed by removal.

ENDOCRINE AND HEMOGLOBIN-RELATED ARTHRITIS AND STORAGE DISEASES

193

Rheumatoid manifestations of endocrine and lipid disease

■ SIMON M. HELFGOTT

- Musculoskeletal abnormalities occur commonly in association with endocrine disease.
- Glandular dysfunction involving the adrenal, pituitary, pancreas, parathyroid, and thyroid may be manifested as rheumatologic disorders.
- Nonspecific rheumatic manifestations and more characteristic abnormalities may occur.
- Musculotendinous, bone, and joint abnormalities are more likely after periods of metabolic imbalance.
- Specific clinical problems (i.e., widened joint spaces, Dupuytren contracture, osteonecrosis, periosteal bone resorption, and muscle weakness) should prompt exclusion of particular disorders.
- Resolution or improvement of the clinical manifestations of rheumatic disease may occur on restoration of metabolic balance.
- Primary hyperlipidemias (hyperlipoproteinemias) result from abnormal metabolism of lipoproteins with an increase in their blood levels.
- Six types of hyperlipoproteinemias are recognized and differ on the basis of their lipoprotein profiles and musculoskeletal manifestations.
- Tendon xanthomas consist of lipid infiltrates, which results in irregular thickening of the involved tendon.
- They may be observed in type IIa and III hyperlipoproteinemia and can be associated with or be preceded by episodes of acute tendinitis, particularly in type IIa.
- Arthralgias or arthritis (or both) can be a feature of type IIa and type IV hyperlipoproteinemia.
- Osseous xanthomas, or aggregates of spumous macrophages, are rare and have been reported mainly in type III hyperlipoproteinemia.
- Hyperuricemia and gout can be associated with the hypertriglyceridemia of types I, IV, and V.
- Sicca-like syndromes, probably caused by fatty infiltration of the lacrimal and salivary glands with subsequent enlargement of the parotids, can develop in patients suffering from type II, IV, and V hyperlipoproteinemia.

ACROMEGALY

The articular manifestations of acromegaly are a leading cause of morbidity and functional disability in affected patients.^{1,2} At the time of diagnosis, most patients have signs or symptoms of joint disease.³⁻⁵ The duration of acromegaly does not appear to correlate with the severity of the arthropathy.³ The initial endocrine changes secondary to acromegaly are followed over time by the development of mechanical changes in the joints and the spine. Joint damage in patients with acromegaly occurs in three stages. The first

is characterized by continued, excessive proliferation and regeneration affecting chondrocyte activity and cartilage matrix growth. In the early course of the disease, elevated growth hormone and insulin-like growth factor type I levels promote the growth of articular cartilage and periarticular ligaments, which leads to cartilage thickening and joint space congestion. In this phase, joint space widening and periarticular soft tissue hypertrophy occur. Hyaline cartilage becomes thickened with clusters of large active basal chondrocytes; marginal osteophyte formation becomes excessive and periosteal fibrocartilaginous attachments hypertrophy and ossify. These changes account for the clinical features of acromegaly: large bones with remodeled shafts; thickened cartilage, tendon, and capsule attachments; and large marginal osteophytes (Fig. 193.1). The second stage consists of the development of specific cartilage ulcers at weight-bearing sites, presumably because of unequal cell proliferation and matrix formation in the cartilage midzone, which creates stress in the interterritorial areas and ultimately cartilage fissuring and ulceration. In the third stage, localized loss of cartilage substance takes place. As a repair mechanism, the resultant regenerating fibrocartilage layer is excessive and striking and forms a layer covering the old hyaline cartilage on the exposed bone. These structural alterations result in eburnation of subchondral bone and cyst formation resembling severe forms of osteoarthritis.

Clinical features

Joint pain is a common finding in patients with acromegaly (Box 193.1). Affected joints include those of the jaw, hands, shoulders, hips, knees, and cervical and lumbar spine (Fig. 193.2). Joint effusions are uncommon; rarely, some patients may experience episodes of pseudogout. Physical examination shows evidence of bony enlargement and soft tissue prominence surrounding affected joints. Radiographs demonstrate widened joint spaces with chondrocalcinosis, osteophyte formation, and calcification of ligamentous insertions. Prognathism is seen commonly and usually accompanied by widening of the interdental spaces.⁶ The Raynaud phenomenon has been described in about a quarter of patients.² Bilateral carpal tunnel syndrome is often present and symptomatic at initial evaluation.⁷ Magnetic resonance imaging has demonstrated increased edema of the median nerve in the carpal tunnel rather than extrinsic compression.⁷ A hallmark feature is vertebral enlargement with widened intervertebral spaces and osteophyte formation; however, facet joint hypertrophy is unusual.⁶ A high prevalence of vertebral fractures has been observed in men and postmenopausal women with acromegaly, regardless of their bone mineral density scores.⁸

DIABETES MELLITUS

Diabetes mellitus is associated with a range of musculoskeletal and rheumatologic problems (Table 193.1). Many studies have observed that the symptoms of hand pain and dysfunction occur more frequently in diabetic patients.⁹ A longer duration of diabetes rather than hemoglobin A_{1c} levels appears to correlate with a higher frequency of hand and shoulder

APPEARANCE OF THE HAND IN ACROMEGALY

Fig. 193.1 (a) Apart from the soft tissue thickening of the hand, this radiograph also shows the increased joint space and enlargement and tufting of the terminal phalanges. (b) Examination of the hand is important for the diagnosis of acromegaly.

APPEARANCE OF THE LUMBAR SPINE IN ACROMEGALY

Fig. 193.2 (a) Typical changes include scalloping of the posterior margin of the vertebrae, new bone formation on the anterior surfaces, and increased intervertebral space. (b) A radiograph of the lumbar spine shows the decrease in disk height because of late degenerative disease.

BOX 193.1 MUSCULOSKELETAL FEATURES OF ACROMEGALY

Clinical features of acromegaly include large bones with remodeled shafts, thickened cartilage, enlarged tendon and capsule attachments, and large marginal osteophytes.

Pain and crepitus are common but rarely accompanied by restricted motion.

Despite frequent back pain, back mobility is maintained even with aging because the thickened intervertebral disk cartilage, together with lax hypertrophied paraspinal ligaments, contribute to increased spinal mobility.

A higher incidence of vertebral fractures may be observed.

TABLE 193.1
Rheumatologic manifestations of diabetes

Disorder	Special features
Adhesive capsulitis	Unilateral shoulder pain Therapies include intraarticular corticosteroids, physical therapy
Limited joint mobility	Painless, "prayer sign" Occasionally associated with hand weakness Correlation with microvascular disease
Dupuytren contracture	Ring, middle finger involvement is more common May be less painful in patients with diabetes
Stenosing tenosynovitis	More common in females Bilateral, multidigit involvement with relative sparing of the index and small fingers
Carpal tunnel syndrome	Similar manifestation as in nondiabetics Bilateral involvement Surgical release may be less effective than in nondiabetics
Calcific tendonitis	Basic calcium pyrophosphate crystal deposition Acute and intensely painful Radiographs may demonstrate calcium deposition within tendons and soft tissues
Diffuse idiopathic skeletal hyperostosis	Seen more commonly in diabetics Typically an asymptomatic finding Anterior ligament ossification on radiographs Peripheral joint calcific enthesopathy
Charcot arthropathy	Unilateral foot involvement, usually the midfoot Seen in the context of severe peripheral neuropathy Osteolysis, joint destruction Role of proinflammatory cytokines?
Muscle infarction	Associated with long-standing disease Pain, swelling, and induration of the thigh High signal intensity noted on T2-weighted magnetic resonance images Resolves over time
Stiff person syndrome	Progressive axial stiffness may lead to an appearance mimicking spine ankylosis. Straightening of the lumbar lordosis "Startle" response (marked hardening of the muscle group in response to fright or surprise) present in most patients Association with raised titers of anti-GAD antibody

GAD, glutamic acid decarboxylase.

syndromes.⁹ A study of adolescents with type I diabetes mellitus found that plantar fascia thickness, as measured by ultrasound imaging, was a significant predictor of the subsequent development of complications in type I diabetes mellitus, thus suggesting that glycation and oxidation of collagen in soft tissues may be independent risk factors for microvascular complications.¹⁰ Similarly, the finding of limited joint mobility of the hands in patients with type I diabetes may indicate an increased risk for microvascular disease.¹¹ Patients with limited joint mobility typically have limited extension of the metacarpophalangeal, proximal interphalangeal, and distal interphalangeal joints, generally beginning in the ulnar digits and spreading

radially.¹² Patients are asked to hold their hands opposed to one another with the wrists extended and the elbows flexed (prayer sign); a positive test is indicated by the inability of patients to completely approximate the palmar surface of the digits. Dupuytren contracture consists of palmar and digital nodules and cords, palmar skin tethering, and digital contractures.¹² In contrast to nondiabetics, the condition is milder, the ring and middle digits are predominantly involved as opposed to the small and ring digits, and few patients complain of symptoms.¹³ Carpal tunnel syndrome has similar findings in diabetic and nondiabetic patients. However, many authors think that diabetic patients have poorer outcomes following carpal tunnel release than nondiabetic patients do.¹⁴

There may be subtle distinctions between the clinical manifestations of stenosing tenosynovitis (trigger finger) in diabetic versus nondiabetic patients. When compared with a nondiabetic population, trigger finger in diabetics is more commonly seen in females and more often bilateral and involving multiple digits with relative sparing of the index and small fingers.¹⁵ Corticosteroid injection is less effective in diabetics, and these patients require surgery more frequently. Adhesive capsulitis of the shoulder can be defined as unilateral shoulder pain of greater than 3 months' duration with an associated reduction in range of motion in all planes by at least 50%.⁹

A study attempting to quantify the prevalence of painful or stiff shoulder in diabetic patients found that shoulder pain was present in about a quarter of the patients as compared with just 5% of nondiabetic individuals.¹⁶ Frozen shoulder was observed in about 4% of patients versus less than 1% in the nondiabetic cohort.

Neuropathic (Charcot) arthropathy is typically characterized by pain and swelling of the midfoot in a patient with underlying peripheral neuropathy. Over time, evidence of severe osteolysis may be seen, and bone and joint destruction may follow. The condition is sometimes self-limited and one sided even though the neuropathy is permanent and symmetric.¹⁷ It has been proposed that activation of proinflammatory cytokines, including tumor necrosis factor- α and interleukin-1 β , together with RANKL-NF- κ B signaling, may result in bone lysis and calcification of the media of the arterial walls of blood vessels supplying the feet.¹⁷

Stiff person syndrome is an uncommon disorder seen in some type I diabetic patients. The condition is characterized by progressive muscle stiffness, rigidity, and spasm involving the axial muscles with severe impairment of ambulation. In severe cases a fixed spinal deformity with pronounced lordosis is evident. The hallmark feature is the presence of superimposed, severe episodic muscle spasm precipitated by sudden movement, noise, or emotional upset (startle reflex). Stiff person syndrome and type I diabetes share some immunologic features, including the presence of antibodies to glutamic acid decarboxylase, although the magnitude of the antibody response and the selected epitopes that are recognized differ in these two diseases.¹⁸

THYROID DISEASE

Disorders of thyroid function can be accompanied by a variety of rheumatologic symptoms ranging from arthralgia and myalgia to weakness and digital vasospasm (Table 193.2). Thyroid deficiency is more frequently associated with musculoskeletal symptoms than hyperthyroidism is. In older patients, hypothyroidism may mimic a polymyalgia rheumatica-like disorder consisting of proximal achiness around the shoulder and pelvic girdle muscles and generalized stiffness. Other patients may have an associated myopathy¹⁹ with findings ranging from mild (delayed tendon reflex response) to severe (weakness, cramps, and severe stiffness). The latter has been termed Hoffman syndrome. This disorder may also be accompanied by muscle hypertrophy (pseudohypertrophy). Most symptoms improve or resolve following correction of the hypothyroidism.¹⁹ Carpal tunnel syndrome may also be associated with hypothyroidism and generally improves with thyroid hormone replacement.²⁰ Myoedema may occasionally be noted when the muscles of affected individuals are tapped with a reflex hammer; the resulting induration persists for several seconds. Rare patients may have a symmetric polyarthritis that involves the metacarpophalangeal and metatarsophalangeal joints, wrists, and knees and resembles seronegative rheumatoid arthritis. Synovial fluid analysis has demonstrated low white blood cell counts and normal fluid viscosity.²⁰

Hyperthyroidism secondary to Graves disease is associated with an unusual cutaneous manifestation known as pretibial myxedema. This dermopathy is an uncommon and late manifestation of Graves disease and is often seen concurrent with the development of Graves ophthalmopathy.²¹ It is generally asymptomatic and manifested as skin induration over the pretibial area, although other areas can be involved as well. The lesion is

TABLE 193.2
Rheumatologic manifestations of thyroid disorders

Manifestation	Hypothyroidism	Hyperthyroidism
Arthralgia, myalgia, achiness, and stiffness	PMR-like manifestation Delayed resolution	Seen at onset Resolves with treatment
Arthritis	Polyarticular MCP, MTP involvement	Acropachy, clubbing
Cutaneous	Raynaud phenomenon	Pretibial myxedema
Myopathy	Proximal, resolves slowly EMG: sensorimotor axonal neuropathy Rarely, "pseudohypertrophy"	Proximal, resolves quickly Sensorimotor axonal neuropathy
Carpal tunnel syndrome	Improves with treatment	Not observed
Vasculitis	Not observed	Rarely seen with the use of propylthiouracil
Bone metabolism effects	Not observed	Increased bone turnover and bone loss
ANA positivity	Occasionally seen	Occasionally seen

ANA, antinuclear antibody; EMG, electromyogram; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PMR, polymyalgia rheumatica.

associated with elevated levels of serum thyroid-stimulating hormone (TSH) receptor antibodies; it has been suggested that TSH receptors in affected skin may serve as antigens driving this immune response.²¹ In some patients with untreated hyperthyroidism, Raynaud phenomenon may be observed.²²

Thyroid acropachy is an unusual manifestation of hyperthyroidism that is always seen in the context of the dermopathy and ophthalmopathy. It is characterized by clubbing of the fingers and toes. The overlying skin may be swollen and tight. Rarely, radiographic evidence of a periosteal reaction involving the distal digital bones may be present.²³ However, unlike pulmonary osteoarthropathy, which it resembles, the bony reaction has a spiculated lacy appearance and is limited to the midportion of the diaphysis with sparing of the long bones.

Myopathy may be present in about 20% of patients in the early stages of hypothyroidism. Patients may complain of proximal weakness, and electromyographic studies have demonstrated a sensorimotor axonal neuropathy.¹⁹ Unlike the myopathy seen with hyperthyroidism, these signs and symptoms resolve immediately with correction of the hypothyroidism. Patients with hypothyroidism also have increased bone turnover and net loss of bone mineral density,²⁴ which resolves with therapy. The drug propylthiouracil, which is often used to treat hyperthyroidism, has been associated with the development of an antineutrophilic cytoplasmic antibody (ANCA)-associated vasculitis.²⁵ ANCA titers are generally markedly elevated and show a perinuclear (p-ANCA) staining pattern. The vasculitis usually resolves with discontinuation of treatment with the drug, although several reports of patients requiring systemic immunosuppressive therapy have been published.²⁶

HYPERPARATHYROIDISM

Primary hyperparathyroidism is now most commonly diagnosed before the onset of overt symptoms; clinically apparent bone disease is uncommon. Parathyroid hormone increases the rate of bone turnover, and its effects on bone may be catabolic or anabolic, depending on the age of the patient, skeletal site, and pattern of serum concentrations of the hormone over time.^{27,28} In general, persistently high serum parathyroid hormone concentrations have catabolic effects on bone, whereas intermittent mild increases have anabolic effects. On balance, the effects of mild primary hyperparathyroidism on bone seem to be slightly anabolic.²⁹ However, the disorder can cause demineralization of bone, distributed variably between cortical sites (i.e., mainly long bones) and trabecular sites (i.e., mainly vertebrae).^{30,31}

With long-standing, untreated severe forms of this disease, osteitis fibrosa cystica may develop. This condition is characterized by bone cysts, brown tumors, fractures, and skeletal deformity. The classic radiographic finding of osteitis fibrosa cystica is subperiosteal resorption of the radial aspect of the index and long fingers. Histologic abnormalities include extensive cortical resorption and tunneling defects lined with osteoclasts. Following successful parathyroidectomy, most of the manifestations of primary hyperparathyroidism, including the skeletal disease, are readily reversed.

Bone disease in patients with chronic renal disease is caused by hyperparathyroidism and other factors.³² Some patients with chronic renal disease have hyperparathyroid uremic bone disease, which is characterized by activation of osteoblasts and osteoclasts with excessive bone resorption. Other patients have an adynamic bone disease or osteomalacia. Adynamic bone disease is characterized by low activity of bone cells, no excessive accumulation of matrix, and little parathyroid hypersecretion.^{32,33} Osteomalacia in renal failure is characterized by excessive accumulation of osteoid and a minimal degree of hyperparathyroidism and has been associated with accumulation of aluminum in bone. This disorder has become less common as a result of minimization of the use of products with high concentrations of aluminum, such as found in some antacids and dialysis fluids.^{32,33} The frequency of hyperparathyroid bone disease in patients with uremia is similar to the frequency of adynamic bone disease.^{32,33} Uremic hyperparathyroid bone disease is best treated by raising serum calcium concentrations and thereby decreasing parathyroid hormone secretion. The cause of adynamic bone disease is not known, and no specific treatment is available.³⁴

Calciophylaxis, or calcific uremic arteriolopathy, is a serious complication of end-stage renal disease that is thought to be due to hyperparathyroidism. Female gender, hyperphosphatemia, and increased serum calcium phosphate product are associated with an increased risk for the development of calciophylaxis. The lesions begin as painful, symmetric violaceous discoloration and evolve into well-demarcated, nonhealing skin ulcers that become necrotic and gangrenous with eschar formation. More distal lesions have been described to involve the calves, forearms, acral areas, and genitalia. The presence of lesions more proximally located on the shoulders, trunk, buttocks, and thighs portends a worse prognosis. Skin biopsy specimens demonstrate extensive calcification of small- to medium-sized arteries or arterioles with intimal proliferation. The calcium deposition may be either segmental or circumferential, and the lumen is generally preserved. Management includes treatment of the ulcers and judicious use of antibiotics. Parathyroidectomy may improve survival.³⁴

In the classic form of pseudohypoparathyroidism (PHP), resistance to the effects of parathyroid hormone is seen in both the skeleton and kidney. The somatic features of Albright hereditary osteodystrophy may accompany the hormonal resistance.^{35,36} This peculiar phenotype, reported in subjects with PHP type Ia, is caused by mutations in the GNAS gene (guanine nucleotide-binding protein α -stimulating polypeptide), which encodes for the α subunit of the stimulatory G protein ($G_s\alpha$). Somatic features of Albright hereditary osteodystrophy, including short stature, short digits, and subcutaneous calcifications or ossifications, may be present. Brachydactyly, classically described as shortening of metacarpals III, IV, and V and distal phalanx I, is the typical and most specific sign of Albright hereditary osteodystrophy. It has been reported in 70% of individuals with PHP on routine radiologic examination.³⁶

ADRENAL DISORDERS

Cushing syndrome is a clinical disorder caused by excessive production of cortisol by the adrenal glands. Proximal lower extremity weakness may be one of the initial clinical symptoms and is generally noted on clinical examination. Electromyographic studies typically demonstrate myopathic changes. On muscle biopsy, atrophy of predominantly type II muscle fibers has been noted.³⁷

Adrenal insufficiency (Addison disease) leading to hypocortisolism has been linked with chronic fatigue and weakness.³⁸ Contractures as a consequence of tendon or skeletal muscle shortening have been reported in individuals with adrenal insufficiency.

LIPID DISORDERS

Heterozygous familial hypercholesterolemia is an autosomal dominant disorder with a prevalence of approximately 1 in 500 individuals, whereas the homozygous form is rarer and involves 1 in 1 million individuals (Table 193.3).³⁹ Abnormal or absent low-density lipoprotein (LDL) receptors cause the accumulation of cholesterol-rich LDL particles. These particles accumulate in tendons, particularly the Achilles, where they are metabolized into oxidized LDL, which is then actively taken up by macrophages within the tendon^{39,40} to form the xanthoma (Fig. 193.3). These structures are composed of lipid and collagen; detailed analysis has demonstrated that the lipid composition is similar to the core of advanced atherosclerotic plaque.³⁹ In fact, there appears to be a correlation between Achilles tendon thickness, as evaluated by ultrasonography, and carotid intima-media thickness in patients with familial hypercholesterolemia.⁴¹ Ultrasonography has fairly high

sensitivity in revealing subclinical xanthomas in some individuals with heterozygous familial hypercholesterolemia for which the diagnosis cannot be established by other means. Xanthomas appear as focal or confluent regions.^{39,40}

A transient polyarthritis involving the knees, ankles, and hands has been described in some patients with familial forms of hyperlipidemia.⁴² Affected patients had moderate pain and swelling and occasional redness of the affected joints. None of these patients had gout. Synovial fluid analysis demonstrated noninflammatory features, including white blood cell counts lower than 200/mm³, and no crystals were seen. The erythrocyte sedimentation rate was always normal.

Rarely, cholesterol crystals may be seen in the synovial fluid of patients with long-standing, severe rheumatoid arthritis. The synovial fluid has a characteristic milky appearance. The crystals may appear in two morphologic forms: (1) flat, rectangular, negatively birefringent plates with notched corners that range from 8 to 100 μ m long and consist of monohydrate cholesterol or (2) rod-shaped helical birefringent crystals ranging from 2 to 20 μ m long and consisting of anhydrate cholesterol.⁴³

STATIN DRUG-ASSOCIATED MUSCLE SYNDROMES

Myopathic syndromes associated with statin therapy range from myalgias to myositis to overt rhabdomyolysis, which may be accompanied by acute renal failure.⁴⁴

Experience in clinical practice suggests that muscle side effects, including those requiring discontinuation of statin therapy, are relatively common. Onset of the muscle symptoms usually takes place within weeks to months after the initiation of statin therapy but may occur at any time during treatment. The myalgia and weakness resolve and serum creatine kinase concentrations return to normal over a period of days to weeks after discontinuation of treatment with the drug.⁴⁵

Statin-induced myalgia is typically manifested as proximal, symmetric muscle weakness and soreness. Muscle tenderness and functional impairments such as difficulty raising the arms above the head, arising from a seated position, or climbing stairs may be noted. Less often the discomfort is asymmetric. Other reported symptoms include cramping and tendon pain. Clinically significant myopathy, defined as an elevation in serum creatine kinase to greater than 10 times normal in association with muscle symptoms, occurred in less than 0.5% of patients in large clinical trials.⁴⁶ The mechanism by which statins cause muscle toxicity is not well understood. They inhibit the conversion of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) to mevalonic acid, which is an important early step in cholesterol synthesis. Statins can also decrease the synthesis of coenzyme Q₁₀ (ubiquinone), which plays an important role in the production of muscle cell energy. It has been speculated that the reduction in coenzyme Q₁₀ may contribute to the statin-induced muscle injury. Some studies have found that statins decrease plasma concentrations of coenzyme Q₁₀.⁴⁷

In large clinical trials, massive rhabdomyolysis with acute renal failure was not seen in patients who did not have other risk factors such as renal failure or concurrent use of cyclosporine, gemfibrozil, macrolide antibiotics, digoxin, antifungal medications, and warfarin. Other possible predisposing factors include hypothyroidism and inflammatory myopathies.⁴⁸

Hemophilia and von Willebrand disease

■ JANE F. BLEASEL

HEMOPHILIA

- Hemophilia is a sex-linked inherited bleeding disorder caused by a deficiency of factor VIII (hemophilia A) or IX (hemophilia B).
- Bleeding occurs either spontaneously or with minor trauma. Recurrent hemarthroses can lead to progressive arthropathy, particularly affecting the ankles, knees, and elbows.
- Treatment involves adequate factor replacement. Prophylactic treatment from a young age is beneficial in preventing hemorrhage and preserving joint function.
- Chemical or radioactive synoviorrhesis is effective treatment of recurrent bleeding and synovitis. Joint replacement or fusion is beneficial for the treatment of chronic, severe arthritis.
- Viral transmission of blood-borne viruses is virtually eliminated with the use of recombinant factor.
- Inhibitor development occurs in about 30% of hemophilia A and 5% of hemophilia B patients and is associated with worse joint outcomes and quality of life.

VON WILLEBRAND DISEASE

- Von Willebrand disease is the most common of the bleeding disorders.
- It is caused by deficiency in von Willebrand factor and characterized by mucocutaneous bleeding.
- Severe forms are associated with hemarthroses.

HEMOPHILIA**History**

The term *hemophilia* (Greek: "love of blood") is attributed to Schönlein in 1818, although his pupil Hopf first referred to it in a dissertation.¹ The disease was well recognized and documented by Jewish religious writers in the fifth century AD because of the hazards of circumcision in hemophilic infants. Albucasis, who documented the deaths of men and boys in a certain Spanish village from uncontrollable hemorrhage after trivial wounds and bleeding, recorded the first published medical recognition of the disorder some 500 years later.

Joint disease secondary to chronic intraarticular bleeding was increasingly noted from the early 19th century onward.¹ The appearance of hemophilia in the British royal family in Queen Victoria's offspring and its transmission to several of the royal families of Europe during the late 19th and early 20th centuries spurred research. The young Czarévitch Alexei's severe hemophilia and the resultant established chronic joint disease distracted his parents and almost certainly altered the course of history in Russia leading up to the revolution of 1917. Elucidation of the underlying coagulation defect and the advent of effective clotting factor replacement during the 20th century revolutionized the management of hemophilia in general and allowed the potential prevention of joint disease and surgical correction of established deformity. Early therapeutic optimism was unfortunately diminished by the high incidence of human immunodeficiency virus (HIV) type 1 infection in patients treated with blood products between 1980 and 1985. The advent of synthetic factor VIII and IX concentrates, together with donor screening and heat treatment of naturally obtained

concentrates, has almost completely prevented this problem, but the recombinant products are still very expensive and not available in most developing countries.

Epidemiology

Hemophilia A has an incidence of 1 in 5000 male births and hemophilia B an incidence of 1 in 30,000. The distribution is generally uniform in the world, and there are no obvious associations with human leukocyte antigens.¹ Because it is X-linked recessive, it is a disease seen almost exclusively in males. However, symptomatic hemophilia may occur in females as a result of X-chromosome inactivation at an unusually early stage of embryogenesis. This will lead to low levels of factor VIII. In addition, if an affected male and a carrier female have offspring, 50% of the resultant female children will be homozygous for hemophilia.

Classification

In primary hemophilia, inherited deficiencies of any of the factors involved in hemostasis can result in bleeding disorders. The most well known are deficiencies in factors VIII (hemophilia A) and IX (hemophilia B).

In secondary hemophilia, factor deficiencies are caused by decreased synthesis, increased clearance, or destruction of clotting factors. The most common mechanism is antibodies (inhibitors) directed against factor VIII, although antibodies can develop to other factors, such as IX, X, or von Willebrand factor. In 50% of cases, no underlying pathologic process is found. Autoantibodies can develop postpartum or be associated with a range of diseases, most commonly autoimmune conditions such as rheumatoid arthritis, systemic lupus erythematosus, and other connective tissue disorders. They can also occur with skin diseases, lymphoproliferative disorders, other tumors, and drugs. The clinical features are similar to those of inherited hemophilias.

Clinical features

Mild, moderate, and severe forms of the hemophilias are defined by plasma coagulation factor levels corresponding to 5% to 40%, 1% to 5%, and 1% or less of normal, respectively. Hemophilic arthropathy is the most important cause of morbidity in patients with severe hemophilia. Bleeding into muscle occurs at about one tenth the frequency of joint hemorrhages.

Some female carriers of the hemophilia genes have relatively low factor levels and may have problems during menstruation and with hemostasis during surgery and dental extractions, but bleeding into joints is exceptionally uncommon.

Acute hemarthrosis

Acute hemarthrosis is the initiating event in hemophilic arthropathy and frequently occurs spontaneously or in response to minor trauma with severe or moderate disease. Patients often describe a tingling sensation and tightness in the joint preceding the clinical signs of hemarthrosis. The joint then rapidly loses range of motion and becomes acutely painful, warm, and swollen. Rising intraarticular pressure eventually terminates the bleeding, and resolution occurs slowly, accompanied by bruising. Milder bleeding episodes may be manifested less dramatically and be limited to the subsynovium or be unrecognized, as is apparently the case when established arthritis develops in a joint without any history of bleeding.

The age at onset and the frequency of acute hemarthroses depend mainly on the severity of the factor deficiency. Levels of 5% of normal or less are almost invariably associated with recurrent hemarthroses, and established arthritis may occur less frequently with levels up to 20%.² Weight-bearing

joints on the dominant side are more commonly affected, coincident with the child beginning to walk. The joints traditionally affected in decreasing order of frequency are those of the knees, elbows, and ankles. However, prophylactic treatment induces a changing pattern of joint involvement, with the ankle surpassing the knee as the most common site of bleeding. Avascular necrosis of the femoral head as a result of hemorrhage into the hip joint may also occur, with the clinical and radiologic features resembling those of Perthes disease.

Differential diagnosis of acute hemarthroses

Occasionally, musculoskeletal hemorrhage is the first indication of the underlying condition, which if not recognized, can result in major morbidity or mortality. In this event the differential diagnosis includes other causes of hemarthrosis, such as joint trauma with intraarticular fractures, bleeding disorders such as platelet deficiencies or anticoagulant therapy, other blood dyscrasias, villonodular synovitis, acute inflammatory arthritides such as pyrophosphate arthropathy in older patients, and rarely, joint neoplasms.

Subacute arthropathy

Subacute arthropathy usually follows repeated hemarthroses and often targets one or several joints, in which bleeding is more frequent ("target joint"). A target joint is defined as a joint in which three or more spontaneous bleeding episodes have occurred within a consecutive 6-month period. A persistent boggy synovitis with synovial thickening, chronic joint effusion, and variable levels of pain in the absence of recent hemorrhage is seen. Muscle weakness and joint laxity contribute to further bleeding from the friable, thickened synovium, which results in continuing damage. The hyaline articular cartilage is progressively eroded by the inflammation associated with iron deposition. Ultimately, deep pits filled with friable blood clot occur in the cartilage, along with a surviving plateau of less damaged articular cartilage. Subarticular cyst formation is common, and cartilage collapse may result in large bony defects.

Chronic arthropathy

The end result after several months to years is a disorganized joint exhibiting bony thickening, deformity, loss of movement, and coarse crepitus as a result of the loss of articular cartilage and sclerosis of subchondral bone. Joint contracture secondary to fibrosis or ankylosis is common. Soft tissue swelling and effusions are rare at this stage, and pain is fluctuating and variable but at times severe.³

Muscle hemorrhage

Muscle hemorrhage may be potentially crippling, such as bleeding into the psoas muscle leading to hip contractures and femoral nerve palsy. Bleeding into the forearm can cause acute compartment syndromes and subsequent ischemic muscle atrophy and nerve damage. At times, large hemocysts develop within muscle (Fig. 194.1).

Hemophilic pseudotumors

Hemophilic pseudotumors may develop in bone and cause locally destructive lesions⁴; one type occurs in peripheral long bones, and the second type is observed around the pelvis. They are rare, with a frequency of about 1% in hemophiliacs. The majority of pseudotumors are due to repeated hemorrhage, either subperiosteally or into adjacent muscle. Subsequently, the hematoma becomes encapsulated and calcified with progressive enlargement. These events are postulated to be due to osmotic gradients across the fibrous capsule of the lesion. In children they tend to be situated distally and result from trauma.

The second type occurs more often in the pelvic region in adults and originates in soft tissues. They may exert pressure on intraabdominal or intrapelvic structures and can also cause bony erosion of the pelvic bones. They do not invade surrounding tissues, thus the name "pseudotumor." Complications of pseudotumors include fistulization to skin or intraabdominal organs, infection, internal bleeding, and even death.

Management depends on the size and location of the pseudotumor. Some distally situated lesions in children are treated conservatively with immobilization and adequate factor replacement. A 6-week course of treatment with factor is recommended in an attempt to shrink the pseudotumor. If this is effective, factor replacement can be continued. Alternative treatment options include surgical removal, injection of fibrin glue, embolization, or radiotherapy.

Diagnosis

The family history is important because in the majority of cases the mother will be identified as the carrier. In a third of cases no family history will be

Fig. 194.1 Hemocyst in the upper part of the left arm.

BOX 194.1 RADIOLOGIC CHANGES OF HEMOPHILIC ARTHROPATHY

Early

Periarticular soft tissue swelling
Periarticular demineralization
Increased radiodensity of thickened synovium* (Fig. 194.2)

Intermediate

Harris (growth arrest) lines
Epiphyseal widening, premature fusion, or both
Widening of the femoral and humeral intercondylar notches*
Squaring of the inferior border of the patella
Ankle deformities—tibiotalar slant (Fig. 194.3a)
Flattening of the talus
Proximal radial head enlargement* (Fig. 194.3b)

Late

Cartilage irregularity and narrowing; central and marginal erosions
Incongruity of joint surfaces
Subarticular sclerosis and osteophyte formation
Subarticular bone cysts
Subluxations, joint disorganization
Bony ankylosis

*Considered to be specific for hemophilic arthropathy.

elicited. This can be due to a spontaneous mutation in the factor VIII or IX gene or multiple generations of female carriers without an affected male. Initial screening tests such as a platelet count, bleeding time, prothrombin time (PT), and activated partial thromboplastin time (APTT) are required. A normal platelet count, normal PT, and prolonged APTT are characteristic of hemophilia A and B. Mild hemophilia B may have a normal APTT, and if there is uncertainty, factor IX assays should be performed. Specific factor assays confirm and quantify the deficiency. In previously undiagnosed cases of joint swelling, joint aspiration will almost certainly be necessary to confirm the presence of blood in the joint.

Imaging

The characteristic radiologic changes described in hemophilic arthropathy are listed in Box 194.1. Many are not specific and occur in other

arthropathies, especially those of childhood, most notably juvenile idiopathic arthritis.

The most widely used classification of the radiologic changes in hemophilic arthropathy is that of Pettersson and coworkers,⁵ with subsequent classifications including clinical criteria.⁶ When surgery is contemplated in patients with pseudotumors, computed tomography (CT) and magnetic resonance imaging (MRI) are indicated to determine the extent of bone and soft tissue involvement, and regional angiography is used to define the vascular supply to the lesion (Fig. 194.4).

MRI has the capacity not only to confirm the presence of blood within the joint cavity or subsynovium but also to detect early changes in hyaline cartilage not apparent on conventional radiographs and to assess the degree of synovial hypertrophy (Fig. 194.5). Gradient echo T2-weighted images can demonstrate iron in the synovium, a hallmark of previous joint hemorrhages. In some countries MRI is considered the method of choice to assess children for early joint changes, and a number of scoring systems for hemophilic arthropathy have been developed in an attempt to standardize reporting of the joint and soft tissue abnormalities. The expense of MRI and its lack of availability in many less affluent countries limit its potential usefulness at present.

Fig. 194.2 Radiograph showing subacute hemophilic arthropathy. Synovial thickening and radiologic density are present because of iron deposition.

Ultrasound has many advantages as it is accessible and relatively cheap. A protocol for scanning the six main target joints and a scoring system has recently been described.⁷ This provides information about cartilage as well as soft tissue structures, and may be particularly useful in assessing joints in younger patients with hemophilia.

Etiology

Bleeding in hemophilia is due to failure of secondary hemostasis. Formation of the platelet plug (primary hemostasis) is normal, but stabilization of the plug by fibrin is abnormal because of inadequate thrombin generation.⁸ Tissue factor VIIa is of critical importance in the initiation of coagulation by activating factors IX and X through the tissue factor VIIa pathway. In addition, its role in the interactions involving factors VIII and IX appears to result in a burst of thrombin generation on the activated platelet surface, which leads to effective blood clotting.

Hemophilia is inherited as an X-linked recessive trait that occurs in two forms—hemophilia A (factor VIII deficiency) and hemophilia B or Christmas disease (factor IX deficiency)—with the ratio of type A to type B being approximately 6:1. Deficiencies in other clotting factors are very rare, although described. The factor VIII gene is situated on the long arm of the X chromosome and is one of the largest genes; it constitutes 0.1% of the X chromosome. It is made up of 26 exons that span 186 kb. The factor VIII gene defects associated with hemophilia can be divided into three groups: (1) gross gene rearrangements, (2) insertions or deletions, and (3) single base substitutions resulting in amino acid replacement, premature peptide chain termination, or mRNA splicing defects. Approximately 45% of cases of severe hemophilia A are caused by a major inversion of a section of the tip of the long arm of the X chromosome, with one breakpoint occurring in intron 22, the so-called flip-tip mutation.⁹ This mutation arises almost exclusively in the male germline. It is now possible to detect the causative mutation in more than 95% of individuals with hemophilia A.

The factor IX gene is also situated on the long arm of the X chromosome and spans 33.5 kb with eight exons and seven introns. Hemophilia B is genetically heterogeneous, and most affected families have a unique (private) mutation. Two thirds of the gene mutations are missense mutations (changing amino acids), with a range of other types of mutation accounting for the other third.⁸ Sequence analysis of amplified fragments that include all eight exons of the factor IX gene can identify a mutation in more than 99% of individuals with hemophilia B. Direct sequencing is the usual approach, although several screening strategies have been used. Knowledge of the causative gene mutation has increased the accuracy of carrier detection and prenatal diagnosis within families and has made genetic counseling more accurate.

Fetal gender can be determined with polymerase chain reaction techniques to identify the Y chromosome in blood samples from the mother after 7 to 9 weeks. Alternatively, ultrasound can identify the sex after

Fig. 194.5 Hemophilic arthropathy of the knee seen on a sagittal proton density-weighted magnetic resonance image. Extensive synovitis of very low signal intensity is present in the suprapatellar recess, consistent with hemosiderin from recurrent hemarthroses (horizontal arrow). In addition, full thickness cartilage loss and subchondral cysts are evident in the lateral compartment of the knee (vertical arrow).

11 weeks. Chorionic villous sampling performed between 9 and 14 weeks is the main method of prenatal diagnosis, or amniocentesis can be done at the later stage of 15 to 17 weeks. All these methods provide the option of termination if acceptable to the parents or help the family and medical specialists prepare and plan for the birth of a child with hemophilia. It is also possible to undergo *in vitro* fertilization treatment to select genetically normal embryos. Preimplantation genetic diagnosis offers families at risk the opportunity to give birth to an unaffected child.^{10,11} Despite these advances, up to 25% of cases of hemophilia occur *de novo* and are not detected by genetic screening in previously unaffected families.

Pathogenesis

The two main characteristic features of hemophilic arthropathy are chronic synovitis and cartilage degeneration. Iron deposition appears to be critical in production of the synovitis (Fig. 194-6).¹² The synovium plays a major role in absorption of blood from the joint after hemorrhage, with progressive accumulation of hemosiderin in synovial tissue leading to chronic inflammatory changes consisting of production of collagenases, proteolytic enzymes, and proinflammatory cytokines, which cause cartilage destruction. Proliferation of the synovium takes place, and neovascularization leads to inflamed, friable tissue more susceptible to bleeding. Thus, a vicious cycle is established with repeated bleeding after minimal trauma.

Blood in the joint has a direct harmful effect on cartilage by inhibiting proteoglycan synthesis and increasing degradation of the cartilage matrix. Chondrocyte apoptosis is increased via the production of toxic hydroxyl radicals induced by cytokines from mononuclear cells. Iron plays a central role in that it catalyzes the formation of oxygen metabolites. *In vivo* studies using a beagle model in which one knee was injected with blood on days 0 and 2 demonstrated that early cartilage changes appear by day 4, before the synovial inflammation is established. The cartilage of young adult dogs was more susceptible than that of older animals.¹³ When blood was injected into

(a) Synovial hypertrophy, monocyte infiltration (long arrow, top right), heavy synovial and subsynovial deposition of hemosiderin (arrowhead, middle right margin, and arrow, lower corner), and new vessel formation (hematoxylin-eosin, original magnification $\times 100$). (b) Iron deposition (Prussian blue, original magnification $\times 100$).

the joint repeatedly and loads placed on the joint, the cartilage showed features of degeneration and synovial inflammation. Ultimately, repeated hemorrhage into a joint leads to dense fibrosis.

Management

The concept of a hemophilia center providing multidisciplinary expertise has been a major advance in hemophilia care. Such centers provide a wide spectrum of medical, nursing, surgical, and allied health professional skills.¹⁴

Prophylactic factor treatment

The idea of prophylactic factor replacement originates from the observation that chronic arthropathy rarely develops in patients with moderate hemophilia and factor levels of 1% to 4%. There is a direct relationship between the number of joint hemorrhages and joint damage, and therefore by giving factor prophylactically, joint bleeding is prevented. Prophylactic treatment with factor VIII or IX is given two to three times weekly to prevent bleeding in severe hemophiliacs. This increases their factor level to more than 1%, thereby converting them to the phenotype of moderate hemophiliacs. This should be the goal to preserve normal joint function in those with severe disease.

Prophylactic treatment can begin at an early age as either primary or secondary prophylaxis. Primary prophylaxis is defined as regular continuous treatment initiated in the absence of documented joint disease (as determined by physical examination, imaging studies, or both) and started before the second clinically evident large-joint bleeding and the age of 3 years. Secondary prophylaxis is defined as initiation after two or more bleeding episodes into large joints and before the onset of joint disease. Tertiary prophylaxis refers to continuous treatment with factor started after the onset of joint disease.

Nilsson and associates¹⁵ reported that if primary prophylaxis is begun at the age of 1 to 2 years, with factor given at high doses on alternate days (factor VIII) or twice weekly (factor IX), virtually no bleeding occurs and the boys maintain normal joints. This is considered “gold standard” therapy. Two randomized trials of prophylactic treatment with recombinant factor VIII have now been conducted and have shown a reduction in the risk for bleeding of between 48% and 82% in children with hemophilia.^{16,17} The study by Manco-Johnson and colleagues also demonstrated an 83% reduction in joint damage as assessed by MRI in the group receiving prophylactic therapy. Prophylactic treatment of severe hemophilia has been recommended by multiple health organizations worldwide. Although such management is ideal, many countries cannot afford the huge cost of this treatment.

Acute hemarthroses

Prompt and adequate treatment of acute hemarthroses is vital. Factor replacement with plasma-derived concentrates, or preferably recombinant factor VIII or IX, is essential. In developed countries such as Australia, boys

TABLE 194.1

Replacement protocols

Indication for treatment	Factor VIII* or IX [†] level (IU/dL)	Duration of therapy (days)
Hemarthrosis	40-60	1-2
Superficial muscle	40-60	2-3
Deep muscle injury with or without nerve injury		
Initial	80-100	1-2
Maintenance	30-60	3-5
Surgery—major [‡]	80-100	
Preoperative	60-80	1-3
Postoperative	40-60	4-6
	30-50	7-14

*The factor VIII dose is calculated by multiplying the patient's weight in kilograms by the factor level (IU/dL) desired, multiplied by 0.5.

[†]The factor IX dose is calculated by multiplying the patient's weight in kilograms by the factor level (IU/dL) desired.

[‡]Continuous infusions may be used to maintain factor levels of approximately 100% perioperatively if available.

with newly diagnosed hemophilia who have not previously received any human plasma products are provided with recombinant factor VIII or IX. This favorable situation is unfortunately not realized in up to 80% of the world's hemophilia patients, who do not receive adequate treatment. Replacement protocols are summarized in Table 194.1.

Although aspiration of all the blood from the affected joint would seem logical given the role of iron in the pathophysiology of hemophilic synovitis and cartilage damage, it is often impractical. Many patients have already received home-based factor replacement, and aspiration may be difficult and, for young patients, quite traumatic. Aspiration is indicated only in the following circumstances: if a tense, painful, bleeding joint shows no improvement 24 hours after conservative treatment; joint pain cannot be controlled; there is evidence of neurovascular compromise; or infection is suspected. If aspiration is required, a large-bore needle such as a 16-gauge one should be used under factor coverage for 48 to 72 hours to raise the factor level to 30% to 50% of normal.

Local treatment initially with rest, ice packs, and analgesics, followed by graduated physiotherapy and factor replacement for 48 hours, is usually effective. Isometric exercises should be started the next day, and graduated active physiotherapy should be encouraged after the first 24 hours, with prophylactic factor replacement if necessary.

Subacute hemophilic arthropathy

The subacute stage of the disease—development of a “boggy synovitis” and characteristic radiographic changes—indicates potential permanent joint damage and necessitates carefully planned management. Prompt treatment of joint bleeding is again vital, and when target joints are emerging, secondary prophylaxis with factor replacement should be initiated. The usual regimen is three-times-weekly treatments for hemophilia A and twice weekly for hemophilia B. Various protocols ranging from 15 to 40 IU/kg per dose are available for prophylaxis. This may be effective in breaking the cycle of recurrent hemarthroses and the development of synovitis and damage.

Physiotherapy to maintain strong muscles around joints is an important component of treatment to minimize bleeding. Nonsteroidal antiinflammatory drugs, specifically the cyclooxygenase-2 inhibitors, are used because they do not cause platelet dysfunction. Intraarticular corticosteroids may provide short-term benefit when total joint replacement surgery is not yet indicated.

Radionuclide synovectomy with intraarticular agents such as yttrium 90 and rhenium 186 is easy to perform and effective in reducing the frequency of intraarticular bleeding in the knee, elbow, shoulder, and ankle.¹⁸ A recent study reported the results of 156 radionuclide synovectomies in 104 joints of 78 hemophiliacs with either yttrium 90 or rhenium 186.¹⁹ Radionuclide synovectomy resulted in significant improvement in the number of hemarthroses, articular pain, range of motion, muscle strength, and degree of synovitis as measured clinically and by radiologic techniques. The number of episodes of hemarthrosis and the level of pain decreased most significantly by 70%. The ideal situation is a patient in whom a target joint with

recurrent hemorrhages and synovitis is developing but without radiologic evidence of damage. Synoviorthesis is particularly useful in patients with inhibitors because it avoids the risk of recurrent bleeding and costly consumption of factor concentrate.²⁰

Yttrium is favored for the knee and shoulder and rhenium for the elbow and ankle. One to three intraarticular injections can be given into any one joint at an interval of at least 3 months. Needle position should be confirmed with fluoroscopic arthrography if its position is at all in doubt. A corticosteroid plus local anesthetic should be injected after the radioisotope to wash out the needle track and prevent potential burn of soft tissues by the radioisotope. The joint should be rested for 24 hours after the procedure, with adequate factor coverage both before and after the procedure. This procedure can be used safely even in young patients.

Intraarticular sclerosants have been used widely in countries in which radiocolloids are not available and include rifampicin, ethanolamine (Ethamolin), and tetracyclines.

Arthroscopic synovectomy is sometimes beneficial when medical synovectomy has failed. Open surgical synovectomy is rarely performed because it is invasive and associated with a reduction in range of motion of the joint.

Chronic arthropathy

Chronic arthropathy represents failure of conservative treatment. With the advent of primary prophylaxis, the hope is that chronic arthropathy will become less of a clinical problem in the future. Pain relief with simple analgesics and nonsteroidal antiinflammatory drugs such as cyclooxygenase-2 inhibitors is essential. Stronger narcotic analgesia and involvement of a chronic pain team may be required for severe, chronic joint disease. Physiotherapy is part of the routine management of all patients with chronic joint disease to maintain muscle strength and prevent contractures. Serial casting, bracing, and orthotics are possible options for conservative management of chronic arthropathy.

Exercise and sports

Physiotherapy, exercise, and sports are essential for maintaining the physical condition and improving the quality of life of individuals with hemophilia.²¹ Improving muscle strength and stability around a joint may prevent injury and bleeding. Exercise may also prevent osteoporosis, which has been shown to be associated with hemophilia. Sporting activity that may lead to joint hemorrhage should be preceded by prophylactic therapy.

A recent prospective case-crossover study of children with hemophilia assessed the risk for bleeding related to physical activity and the use of clotting factors.²² One hundred four children between 4 and 18 years of age with moderate or severe hemophilia A or B were monitored for 4839 person-weeks. The median incidence rate (bleeding episodes per year) was 4.3 for participants receiving on-demand therapy and 3.0 for those receiving prophylaxis.

The most common sites of bleeding were the knees (15%), ankles (15%), and elbows (10%), with the frequency of bleeding highest before and after school. Not surprisingly, the study demonstrated that more vigorous activity

was associated with a transient increased risk for bleeding. When compared with inactivity or low-contact sports (e.g., swimming), the odds ratio was 3.7 for category 3 sports (e.g., wrestling) and 2.7 for category 2 activities (e.g., basketball). The risk for bleeding was reduced by approximately 2% for every 1% increase in clotting factor levels. However, the absolute increase in bleeding risk associated with physical activity was small.

Management of specific sites

The knee is commonly severely damaged in patients who have had recurrent hemorrhages followed by chronic synovitis and secondary osteoarthritis. When pain, fixed deformities, and disability interfere with the patient's life and work, joint stabilization or total joint replacement should be considered. Arthrodesis of the knee in a hemophilia patient remains a sound procedure, with predictable, lasting results and few complications.

Total knee replacement has been used successfully (Fig. 194.7), particularly in patients with severe bony changes, but it is a technically difficult operation because of soft tissue contractures, subchondral bone loss, and deformity. Continuous passive mobilization is generally begun postoperatively. Continuous intravenous infusion of factor VIII or IX before and after surgery to raise factor levels to around 100% is recommended. The improvement in range of movement after total knee replacement is not generally as significant as in nonhemophiliacs, but a reduction in the almost invariable preoperative fixed flexion deformity and a decrease in pain make this procedure very effective. The prosthesis survival rate has varied between studies, with rates of 83% and 89% reported at 10 years.^{23,24} The main reasons for prosthesis removal were infection and aseptic loosening. It has been suggested that continuous infusion of factor replacement during the preoperative, perioperative, and early postoperative phases to maintain levels close to 100% may result in better outcomes.

The ankle joint is rapidly overtaking the knee joint as a source of disability in hemophilia. The development of tibiotalar slant (see Fig. 194.3a) from medial tibial overgrowth results in valgus tilt at the ankle. Avascular necrosis of the talus may also occur and produce dome flattening and collapse, followed by advanced radiologic changes of secondary osteoarthritis. These changes are associated with severe symptoms and often occur despite few documented episodes of intraarticular bleeding. The subtalar joint is affected later in the disease process.

Conservative treatment includes the use of shock-absorbing insoles or heel pads, suitable footwear, and avoidance of sports associated with high impact on the ankle. Arthroscopic débridement or removal of osteophytes at the anterior aspect of the distal end of the tibia may have a role in patients with secondary degenerative changes. Ankle arthroplasty is available in limited units around the world with only short-term follow-up.²⁵ Ankle fusion remains the most reliable form of surgery for chronic arthritis. Usually, range of motion in the ankle at this stage is limited to a few degrees of painful movement, so pain relief at the cost of little increased disability is beneficial.

The elbow is a relatively common target joint for bleeding and chronic joint disease. It is often associated with flexion deformities, limited

Fig. 194.7 Chronic hemophilic arthropathy. Radiographs show chronic hemophilic arthropathy and joint destruction of the knee (a) and the consequent arthroplasties (b).

pronation and supination, and marked wasting of surrounding muscles. Radionuclide synovectomy with image intensifier- or CT-guided injection is an option. Arthroscopic synovectomy of the elbow and excision or trimming of the often enlarged radial head can also be done. Total elbow replacement is the final solution for severely arthritic joints.²⁴ The hip is rarely affected (approximately 4% of patients). However, should the hip be severely arthritic, total joint arthroplasty is indicated, and good results have been reported.

Despite the potential problems with joint replacement surgery, such as bleeding, infection, and restricted range of movement, satisfaction with this procedure by hemophiliacs is high. Studies of HIV-infected patients undergoing total joint replacement have not demonstrated increased risk for prosthetic joint infection relative to HIV-negative hemophiliacs.²⁶

It is essential that orthopedic surgery in hemophilia patients be performed in major hemophilia centers by operators experienced in surgery for the condition and with the full backup of expert hematologic support, adequate laboratory facilities, and secure supplies of appropriate factor replacement.

Complications

Osteoporosis

Although periarticular demineralization is a radiologic feature of hemophilic joints, generalized osteoporosis as a result of chronic hemophilic arthropathy has been reported. An increased number of affected joints and chronic arthritis with coexistent muscle wasting are associated with lower bone density. Baseline treatment with adequate calcium and vitamin D is essential, and bisphosphonates should be used if required. Prophylactic factor treatment from an early age may prevent the development of osteoporosis.

Chronic pain

Control of the pain of chronic hemophilic arthropathy is often a significant problem. The pain can be severe and persistent, and narcotic addiction in severely affected hemophiliacs is not uncommon and best managed in a consultative situation. Cooperative effort of the pain clinic, liaison psychiatrist, social worker, family members, and most importantly, the patient is essential.

Blood product-transmitted infections

The hazards of transmission of infective agents, including HIV and hepatitis B and C viruses, via blood products are well known. With the advent of careful screening of blood products, effective virucidal techniques, and the use of recombinant factor, the risk has been almost eliminated. Management of HIV infection should be the same as in a nonhemophilic patient, and none of the currently available HIV drugs are contraindicated in people with hemophilia. Hepatitis C should be managed, if indicated, with pegylated interferon and ribavirin, and a sustained virologic response is achieved in 61% of hemophiliacs. Prion-mediated disease through plasma-derived products is also a potential risk, but no reliable screening tests are available. New synthetic factor replacements should prevent these and other rarer infective complications. It should be remembered, however, that more than 40% of countries reporting data to the World Federation of Hemophilia in 2010 indicated that they were still using cryoprecipitate from fresh frozen plasma to treat patients with hemophilia.

Coagulation factor inhibitors

Inhibitors refer to IgG antibodies that neutralize clotting factors. With the advent of modern factor replacement and viral inactivation, inhibitors represent the most severe treatment-related complication. Coagulation factor inhibitors occur in 20% to 30% of patients with severe hemophilia A and in 5% of those with hemophilia B. Inhibitors come in two varieties: low-titer inhibitors, which are often overcome by increasing the dose of factor VIII or IX, and high-titer, highly responding antibodies that react with factor VIII or IX to render it ineffective.⁸ A low-level inhibitor is defined as one that is less than 5 Bethesda units (BU), whereas a high-level inhibitor is greater than 5 BU. The presence of an inhibitor should be suspected if a patient fails to respond clinically to clotting factors. Patients with inhibitors have worse joint outcomes and quality of life than do those without inhibitors because of more joint hemorrhages and the development of chronic joint disease.

Treatment of patients with inhibitors involves two aspects: management of acute bleeding episodes and attempts to reduce inhibitor production by induction of immune tolerance. In some cases, porcine factor VIII has been effective in treating patients with inhibitors. The main avenue for treatment of bleeding episodes involves the use of agents that "bypass" the need for factor VIII or IX, such as activated prothrombin complex concentrates (APCCs). The alternative is recombinant activated factor VIIa (rFVIIa),

which avoids the use of pooled plasma. Both agents can be used for acute hemorrhages, prophylaxis, or major surgery in hemophilia A and B patients with inhibitors. The efficacy of two doses of rFVIIa and one dose of APCC for the management of joint bleeding has been demonstrated to be equivalent.²⁷ Secondary prophylaxis with rFVIIa has been shown to reduce the frequency of hemorrhages and decrease hospital admissions and days absent from work or school.²⁸

Patients with highly responding inhibitors can also undergo induction of immune tolerance with high doses of factor VIII/IX, sometimes in combination with cyclophosphamide, high-dose immunoglobulin, protein A immunoadsorption, or rituximab, with success rates of inhibitor eradication with rituximab ranging from 50% to 80%.²⁹ Induction of immune tolerance has been limited because of cost and some doubts about its long-term efficacy.

With the advent of new factor concentrates, risk for the development of inhibitors when changing from one product to another has been reported. These patients need to be monitored for inhibitor development and the new product withdrawn if required, which often leads to disappearance of the inhibitor.

Future treatment options

The ideal treatment of hemophilia would involve the *in vivo* synthesis of adequate amounts of factor VIII or IX. Genetic engineering resulting in gene insertion therapy in which suitable cells containing the appropriate portion of the normal X chromosome are introduced into the body is technically feasible but still elusive despite recent optimism. In animal studies, therapeutic levels of factor VIII and IX have been achieved in mice, dogs, and monkeys by using either mammalian cell lines or viruses as vectors to introduce appropriate genetic material.³⁰ Clinical trials have failed to achieve significant factor VIII expression in hemophilia A patients, but one trial showed transient increased expression of factor IX in hemophilia B patients.³¹

The inconvenience and hazards of repeated intravenous infusion mean that any noninvasive method of delivery would be a major advantage. The search for alternative nonvenous routes of access for coagulation proteins has a long history, but thus far novel techniques such as the oral administration of factor VIII trapped in liposomes have not proved therapeutically effective, and subcutaneous bolus injections have similarly been ineffective.

Summary

The prevalence of severe hemophilic arthropathy has decreased since the introduction of prophylactic therapy from an early age. Many issues related to the optimal treatment of hemophilic synovitis still remain unanswered, but new developments in orthopedic surgery on the elbow and ankle joints have emerged. The development of inhibitors has become an increasing issue, with worse joint outcomes and great expense involved in the use of bypassing agents.

This chapter has been written from the perspective of the treatment available in affluent, largely Western societies and paints a very favorable prognosis for young hemophilia patients in this situation. Hemophilia is distributed ubiquitously, and the reality of the situation is that probably 80% of those with the condition worldwide do not receive adequate treatment, if any, even if the diagnosis has been made.

VON WILLEBRAND DISEASE

Von Willebrand disease (VWD) is the most common of the bleeding disorders and occurs in approximately 1% of the population. Many of these individuals do not come to clinical attention because they fall into the mild end of the disease spectrum. VWD is caused by a deficiency in von Willebrand factor (VWF), which has an important role in both primary hemostasis and formation of the fibrin plug. VWF binds to both platelets and the endothelium at sites of injury and forms an important bridge to aid in platelet clotting. It is also bound to factor VIII as a carrier protein. In the absence of VWF, factor VIII has a markedly reduced half-life with decreased measurable factor VIII levels.

VWD occurs in males and females at a frequency of 1 in 1000, with variable inheritance patterns depending on the subtype. The clinical features of VWD are primarily due to mucocutaneous bleeding. Certain more severe forms of VWD can also result in joint hemorrhages indistinguishable from those in patients with hemophilia A and B.

Joint and bone lesions
in hemoglobinopathies

■ KARLENE HAGLEY ■ KAREL DE CEULAER

- Hemoglobinopathies result from a defect in the synthesis and structure of hemoglobin.
- Rheumatic manifestations in hemoglobinopathies are found mostly in sickle cell disease, usually in homozygous hemoglobin SS disease, hemoglobin SC disease, and S- β -thalassemia.
- Sickle cell trait does not cause rheumatic disease.
- Hemolytic anemia is present along with systemic and rheumatologic manifestations.
- Specific bone and joint lesions include painful crises, dactylitis, and osteonecrosis.
- Other features include osteomyelitis and gout.

INTRODUCTION

Of the known hemoglobinopathies, specific rheumatic complaints are caused mostly by the spectrum of sickle cell disease (SCD). Other hemoglobinopathies (e.g., thalassemias, hemoglobin CC) cause joint disease rarely, mainly through hemochromatosis. Homozygous SCD (SS), the most common phenotype, results from a single nucleotide substitution in each β -globin gene (the normal codon GAG at position $\beta 6$ has been replaced by GUG); this results in substitution of valine for glutamic acid (Glu). When lysine replaces Glu at $\beta 6$ in one chain, hemoglobin C is formed. β -Thalassemia results from synthetic defects in one or more β units of hemoglobin, which causes the clinically significant thalassemia major and intermedia and typical bone marrow deformities.

Under various conditions, hemoglobin S forms liquid crystals that deform erythrocytes into rigid sickle-shaped cells. Vasoocclusion of the microvasculature caused by sickled red blood cells may lead to a variety of joint and bone abnormalities, among which painful crises, dactylitis, and osteonecrosis are the most common. Other major complications include osteomyelitis and gout. Though most frequent in SS disease, all these complications may also occur in other sickle hemoglobinopathies, such as S- β -thalassemia and sickle cell hemoglobin C (SC) disease.

In sickle cell trait, red cell sickling occurs only in nonphysiologic conditions. Therefore, rheumatic complaints should never be ascribed to the presence of sickle cell trait. Many patients with fibromyalgia or connective tissue diseases (CTDs) believe that their sickle cell trait, discovered during routine blood analysis, is the cause of their symptoms. Media reports on the frequency of sickle cell trait in various populations have contributed to this false impression.

It is a common misconception that sickle hemoglobin occurs only in people of African ethnicity. It is also found in people from southern Italy, northern Greece, southern Turkey, Saudi Arabia, and central and southern India. In cases of unexplained bone pain and avascular necrosis, screening with the sickle cell test should be performed on a wide variety of patients. If positive, it should be followed by hemoglobin electrophoresis.

PATHOGENESIS

Polymerization of hemoglobin S in a deoxygenated state leads to decreased red blood cell deformability¹ and sickled cells and is influenced by various

factors, including the intracellular concentration of hemoglobin S, the concentrations of hemoglobin F and C, the presence of β -thalassemia, and the ameliorating presence of α -thalassemia. Other factors are the oxygen saturation of blood, pH, ionic strength, temperature, plasma viscosity, and 2,3-diphosphoglycerate. Alterations in the vascular endothelium (VCAM-1, E-selectin) interact with sickled cells (expressing VLA-4, ICAM-1) and several activated blood cells (certain young red blood cells or "stress reticulocytes," leukocytes, platelets) via an inflammatory reaction, and several cytokines are generated, thus further promoting sickling.² Hemolysis depletes nitric oxide, which reduces vasodilating capacity and results in a subsequent imbalance with endothelin-1 and its vasoconstricting role. All these factors tend to be compounded, and once a sufficient number of rigid sickled cells with polymerized hemoglobin are created, microvascular occlusion will occur with subsequent hypoxia and damage to the tissues supplied. The impact on affected bone is increased intramedullary pressure, bone pain, and potential bone infarction with necrosis.

The increased incidence of *Salmonella* osteomyelitis in SS disease seems to be affected by organism endemicity, asplenia with defective opsonization, and bone necrosis.

Hyperuricemia and gout are caused by decreased renal tubular excretion of urate rather than by urate overproduction secondary to increased purine turnover. Hyperuricemia may contribute to the decreased renal function observed in sickle cell patients older than 40 years.

CLINICAL FEATURES

Painful crisis

Painful crises are the most characteristic musculoskeletal complication of sickle cell hemoglobinopathies³ and account for the majority of all visits for acute medical care and hospital admissions. The event is caused by vasoocclusion in bone marrow. Pain occurs most frequently in the juxtaarticular areas of long bones, but also in the back, ribs, and occasionally the abdomen. Acute low back pain may be the only feature. Frequently, multiple sites are involved, sometimes in a symmetric fashion; the pain may spread from one area to another in an additive or migratory pattern. Localized swelling may be pronounced, especially at the tibial epiphysis. Rib involvement causes pleuritic chest pain. During the painful crisis one or more joints may become inflamed.⁴ The duration of painful crises varies from 10 minutes to several weeks, but persistence of pain beyond 2 weeks is rare with uncomplicated painful crises.

A severe painful crisis usually consists of four distinct clinical phases. During the prodromal phase, the patient becomes restless and experiences vague feelings of being unwell. The second phase (initial phase) is characterized by sudden pain of increased intensity that reaches its maximum during the established phase. Clinical evidence of increased jaundice may be noted. During the resolving phase the pain gradually decreases, and by 2 weeks a steady state is restored in most patients.

Factors precipitating painful crises include dehydration, infections, exposure to cold, pregnancy, emotional stress, and traveling at high altitude. Painful crises are less frequent in female than in male patients; in the latter, a strikingly steep increase in incidence is seen between the ages of 15 and 25 years (Fig. 195.1). Pain frequency correlates with high total hemoglobin levels and low fetal hemoglobin.⁵ SS patients older than 20 years with a high frequency of painful crises have higher mortality than do SS patients with a fewer number of painful episodes.⁵ Occasionally, myonecrosis and myofibrosis have been observed.

Fig. 195.1 The figure shows the incidence of painful crises according to age in male patients and nonpregnant female patients. In female patients there is little age-related change, whereas in male patients the incidence increases dramatically between 15 and 25 years of age and falls again after the age of 32 years. (Adapted from Baum KF, Dunn DT, Maude GH, Serjeant GR. The painful crisis of homozygous sickle cell disease. *Arch Intern Med* 1987;147:1231-4.)

Fig. 195.2 Shortened fingers as a result of premature fusion of the epiphyses of two metacarpal bones. Careful examination of the position of the metacarpophalangeal joints will reveal which bone is affected.

Dactylitis

In young children, vasoocclusion frequently occurs in the bones of the hands and feet and leads to dactylitis (also called *hand-foot syndrome*). This complication typically occurs between 6 months and 2 years, but cases have been described in children up to 7 years of age. Clinical examination reveals acute, painful, nonpitting swelling of hands and feet. The symptoms may improve after 1 week, but recurrences are common. The dactylitis usually heals without sequelae, but occasionally, necrosis of the central part of the epiphysis may lead to premature fusion and shortened digits (Fig. 195.2). This results in disruption of the continuity of alignment of the metacarpophalangeal joints.

Osteonecrosis

Osteonecrosis of the femoral head develops in up to 20% of patients with SS disease and has been diagnosed as early as 5 years of age. At onset the pain is indistinguishable from a painful crisis, but the symptoms do not disappear after 2 weeks and usually worsen with walking and at night. With continued weight bearing the pain increases because of progressive collapse of the femoral head. The final outcome is related to the age of the patient, the timing of diagnosis, and subsequent management. Children may retain

normal hip function despite flattening of the femoral head, whereas adults tend to show progressive deterioration in joint function. Initially, hips affected by osteonecrosis may be asymptomatic. However, 91% of these asymptomatic hips become painful and 77% show collapse. Therefore, early surgical treatment and physiotherapy should be recommended.⁶ Osteonecrosis of the femoral head secondary to hemoglobinopathy is virtually absent in patients with SC disease and S- β -thalassemia who are younger than 15 years. In contrast, the rate of osteonecrosis in older patients (older than 35 years) with SC disease is strikingly similar to that in SS disease.

Osteonecrosis is not limited to the hip joint. Shoulders affected by osteonecrosis tend to show limited function rather than pain because of the absence of weight bearing. Multifocal osteonecrosis may occur in more than 25% of patients. It is therefore important to obtain radiographs or perform magnetic resonance imaging (MRI) of any symptomatic joint in a patient with osteonecrosis of the hip. It is also good practice to order radiographs and MRI scans of the hips in any sickle cell patient in whom joint osteonecrosis is diagnosed.⁷

Osteomyelitis and septic arthritis

Osteomyelitis, when it occurs, usually follows a painful crisis episode. It should be suspected if the patient's temperature exceeds 38° C, when bone pain is present and swelling affects one single site, or if the painful crisis lasts longer than 2 weeks.⁸ A corrected white blood cell count greater than 15,000 also tends to be present. Less commonly, multiple sites of involvement may occur and be manifested in a symmetric pattern. Soft tissue swelling and persistent pyrexia are noted frequently. Osteomyelitis may be complicated by osteonecrosis of the adjacent joint, adhesive capsulitis of the shoulder, and pathologic fractures. The development of chronic osteomyelitis (Fig. 195.3) significantly increases the morbidity of affected patients. *Salmonella* remains the most common organism causing osteomyelitis in SS disease.⁹ The second most frequently seen organism is *Staphylococcus aureus*, with *Pseudomonas aeruginosa* being third.¹⁰ It is possible that chronic sickling of the intestine's vasculature predisposes the devitalized bowel to invasion by enteric bacteria.

Septic arthritis is uncommon in SS disease. It may occur in the presence of acute osteomyelitis, but more commonly it occurs secondary to hematogenous spread, both in children and in adults. In a review of adult patients with SCD, 3% had septic arthritis, 95% of whom had hemoglobin SS¹¹; hip infections predominated (61%) and 88% of all septic arthritis cases appeared to have been blood-borne. Gram-negative infections predominate, especially *Salmonella* in children, but *S. aureus* is also common. Because of recurrent episodes of bone pain and occasionally associated osteonecrosis, septic arthritis may proceed for days without early diagnosis despite marked joint swelling and tenderness. A high index of suspicion in patients with known hip osteonecrosis who experience fever and a sudden increase in hip pain and disability, as well as in those with overt swelling of other peripheral joints, is essential, and such patients should be investigated.

The diagnosis of tuberculous arthritis of a hip affected by avascular necrosis is particularly difficult because of its insidious onset and the radiographic changes associated with the preexisting disease. A positive skin test for tuberculosis may be suggestive, but synovial biopsy and culture are mandatory when the diagnosis is suspected.

Gout

Gouty arthritis is rare in SS disease¹² despite the fact that hyperuricemia occurs in more than 40% of these patients. In contrast to primary gout, involvement of the big toe is less frequently seen than arthritis of the knees, wrists, and small finger joints. Tophaceous gout is extremely uncommon.

Miscellaneous

Chronic arthritis with rapid chondrolysis of the hip may be related to the increased phagocytic activity in some sickle cell patients.¹³ Occasionally, chronic synovitis with pronounced lymphocytic and plasma cell infiltration of the synovium and early cartilage destruction has been noted. Bilateral protrusio acetabuli may result from osteoporosis because of the expanded marrow. Arthritis of the ankle may develop in association with an ischemic ulcer at the medial or lateral malleolus⁴ and tends to occur at the early stages of impending leg ulceration, when the skin surface is still intact but the tissues look shriveled and hyperpigmented. Gait is impaired, and nonsteroidal antiinflammatory drugs (NSAIDs) result in fast improvement of function. If left untreated, the pain and dysfunction of the ankle lessen when the leg ulceration develops, but persistent limitation is common as long as the ulcer persists.

Fig. 195.3 (a and b) Chronic osteomyelitis with periosteal reaction, sclerosis, and sequester. Some sclerosis may be due to previous ischemic crises.

Fig. 195.4 Rheumatoid erosion of the lateral condyle of the knee in a patient with sickle cell disease.

Thalassemia major symptoms usually occur before 3 years of age, whereas thalassemia intermedia manifests later in life. Poor development of the musculature, growth retardation, and skeletal changes, such as long-bone deformities of the legs and craniofacial changes (skull bossing, prominence of the malar eminences, nasal bridge depression, and maxillary hypertrophy), occur.¹⁴ These features are more marked in thalassemia major.

Rheumatoid arthritis rarely develops in patients with hemoglobinopathies, but it has been reported in those with β -thalassemia and SS disease¹⁵ (Fig. 195.4). It is not clear whether this is due to early mortality or factors preventing synovial proliferation. One report noted two patients with SCD (SS) and juvenile idiopathic arthritis¹⁶; a chronic asymmetric seronegative oligoarthritis may also develop in SS patients and needs to be defined. The coexistence of SS disease and systemic lupus erythematosus (SLE) does not occur frequently enough to allow speculation about complement abnormalities in SS disease leading to the development of SLE. High titers of autoantibodies with various immunofluorescence patterns have been reported,¹⁷ but this has not been shown to have a significant association with clinical autoimmune disease and may reflect only immune dysfunction.

INVESTIGATIONS

A complete blood count and reticulocyte count should be obtained with every painful crisis because of possible associated aplastic crisis. Aplastic crisis can be caused by concomitant parvovirus infection. Determination of white blood cell counts by Coulter counter methods should always be followed by a corrected white blood cell count because any immature nucleated red blood cells detected are read as leukocytes. An increasing erythrocyte sedimentation rate (ESR) and leukocytosis with a left differential shift suggest local or systemic infection, possibly osteomyelitis. In uncomplicated SS patients the ESR is usually low because of the unique rheology of sickled red blood cells, but it may rise during the resolving phase of the painful crisis and to a greater extent if infection is present. Determination of C-reactive protein is more reliable than the ESR when monitoring an inflammatory process.

No radiographic changes are typical of uncomplicated painful crises, but periosteal reaction can be seen. Blood cultures should be performed if the patient's temperature exceeds 38° C. Joint aspiration is necessary for painful crisis with associated arthritis. In uncomplicated arthritis, the synovial fluid is noninflammatory, straw colored, and sterile. Blood cultures are always indicated for dactylitis because *Salmonella* infections have been documented in patients with this complication.¹⁸

Radiographs of affected bones are not helpful in the early stages of osteomyelitis, and such changes are apparent only after weeks of illness. Plain radiographs and bone scans are unable to differentiate between painful crises and osteomyelitis. At present, soft tissue ultrasound and gadolinium-enhanced MRI are the best imaging techniques to suggest bone infection, although the exact specificity of these investigations is not yet clear. With ultrasound, a 4-mm depth or more of subperiosteal fluid is highly suggestive of osteomyelitis.¹⁹ On gadolinium-enhanced MRI, acute infarcts demonstrate thin, linear rim enhancement, whereas osteomyelitis shows more geographic and irregular marrow enhancement.²⁰ Patients with osteonecrosis of the femoral head can be staged radiographically by the Steinberg classification system.²¹ In the early stages findings on plain radiographs are normal, but the hip is symptomatic with groin or thigh pain, which is worse at night (Steinberg stage 1). However, MRI can detect abnormalities at this stage, even where bone scans fail. Because of an overall reported sensitivity of 91%, MRI should be performed if avascular necrosis is suspected. Stage 2 hips show sclerosis and radiolucent areas on radiographs (Fig. 195.5), with the symptoms being similar to those in stage 1. In stage 3, plain films show a lucent subchondral line, followed by a cortical discontinuity (crescent sign); it appears only after several weeks of illness. At this stage the pain and limitation have increased and ambulation may be possible only with a cane. Stage 4 is characterized by segmental flattening of the femoral head without radiologic evidence of acetabular involvement (Fig. 195.6). Stage 5 shows progressive destruction of the hip joint with joint space narrowing, cyst sclerosis, and osteophytes (Fig. 195.7). Stage 6 includes advanced degenerative joint disease with extreme narrowing or obliteration of the joint space. It is important to recognize that correlation between the clinical symptoms and radiologic features of osteonecrosis is poor.

The diagnosis of gouty arthritis should be made only after identification of urate crystals in joint fluid. Indeed, hyperuricemia is common in uncomplicated SS disease and therefore cannot be used as a criterion for the presence of gouty arthritis.

DIFFERENTIAL DIAGNOSIS

A painful crisis can mimic attacks of rheumatic fever, which typically starts as a migratory polyarthritis. In both diseases, cardiac murmurs are extremely common (SS patients often have left ventricular hypertrophy and flow murmurs as a result of chronic anemia), and mild elevations in antistreptolysin O are seen frequently. Of note, these conditions may also coexist, especially in developing countries where rheumatic fever is not uncommon.

Fig. 195.5 Very early osteonecrosis of the femoral head (Steinberg stage 2). The femoral head shows sclerotic and radiolucent areas.

Fig. 195.6 Osteonecrosis of the femoral head (Steinberg stage 4). Mild flattening of the superolateral part of the femoral head is present despite long-standing disease.

A chronic destructive synovitis has been described in SS disease and needs to be differentiated from rheumatoid arthritis.

Despite a lack of evidence of an increased frequency of SLE in SS disease, SS patients may frequently be positive for low-titer antinuclear and antiphospholipid antibodies. It needs to be established whether the latter antibodies are contributing to the acute chest syndrome, strokes, and recurrent miscarriages, which are common complications of SS disease.

Fig. 195.7 Advanced osteonecrosis of the femoral head (Steinberg stages 5 and 6). Gross destruction and remodeling of the femoral head are evident. The osteoarthrotic changes are significant.

MANAGEMENT

Management of an acute painful crisis depends on the patient's response to analgesics during previous crises, the severity and extent of the painful episode, and the presence of complications such as acute chest syndrome and paralytic ileus.²²

Because of associated dehydration, administration of large amounts of fluid intravenously at 3 to 4 L/24 hr and unlimited amounts orally have been the standard. However, it has been shown that the majority of uncomplicated painful crises can be managed effectively by oral hydration and analgesia alone. Mild painful crises respond to simple analgesics such as acetaminophen (paracetamol), but with a severe crisis, narcotic analgesics are necessary. In those with normal gastrointestinal motility, oral, controlled-release morphine is a reliable, noninvasive, and preferred alternative.²³ Narcotic analgesics should be prescribed at full therapeutic doses at regular 2- to 4-hour dosing intervals to relieve pain and not be restricted to an as-needed basis. Smaller additional doses should be prescribed for breakthrough pain. The severity of the pain and its response to treatment should be reassessed frequently. NSAIDs, sedatives, antiemetics, and antihistamines may reduce the amount of narcotics needed for the treatment of a painful crisis and can be used in combination with narcotics. Tramadol, a centrally acting analgesic that is administered orally, induces minimal respiratory depression and is useful in the outpatient management of vasoocclusive crises. Antisickling agents and pentoxifylline have shown disappointing results once the pain has begun.

With the recurrent nature of the pain, sickle cell patients may be at risk for addiction and drug dependence, but such risk is much lower than expected. Paranoia about this issue has often led to suboptimal treatment of painful sickle cell crises with unnecessary suffering by patients. Reluctance of hospital staff to prescribe and administer narcotic analgesics is seen by patients as a sign of indifference and perpetuates a lack of confidence in caregivers.

Although in the past most patients with moderate or severe painful crises were treated as inpatients in the hospital, recent studies have shown that daycare centers may provide an adequate alternative way of treating patients with SS crisis.²⁴ Hospitalization has been suggested because of concern for undetected infection and SS-related complications and because of the perception that adequate pain relief can rarely be achieved on an outpatient basis. However, a specialized daycare unit will be able to assess patients more rapidly and titrate the analgesia to individual needs. It may avoid the suboptimal treatment that commonly occurs on hospital wards. However, when systemic infection is suspected, the patient should be admitted for

intravenous antibiotic treatment, in addition to analgesic medication. Another indication for hospitalization is extensive associated chest syndrome, in which early exchange transfusion could be life-saving.

Attention should be paid to prevention of painful crises, including life-style changes (avoidance of stress, alcohol, overexertion, swimming, getting caught in the rain, high altitudes) and medications. Hydroxyurea increases the concentration of hemoglobin F, along with a moderate reduction in neutrophils, reticulocytes, and young, low-density SS red blood cells. Clinically, hydroxyurea has been shown to reduce the frequency of painful crises in adult SS patients and is cost-effective.²⁵

If osteonecrosis of the femoral head is documented, the patient should be maintained on complete bed rest and totally avoid weight bearing. In children this can be achieved by casting with the knee immobilized at a 30-degree angle. Another option to avoid bearing weight is crutches. Only when severe chronic hip pain is not controlled by medical treatment and when the femoral head is severely damaged (Steinberg stage 5 or 6) is a total hip replacement indicated. Indeed, the results of total hip replacement in SS patients are much less favorable than in patients with osteoarthritis. Apart from perioperative complications, loosening of the prosthesis and infection cause poor long-term replacement outcomes when compared with primary degenerative hip disease.^{26,27} However, in a more recent study, the rate of postoperative infections was reduced to 3% and long-term loosening of the prosthesis to 8% for the cup and 5% for the stem.²⁸ Despite an improved outcome with total hip arthroplasty, attention should be directed to detection of osteonecrosis at an early stage and prevention of progression with conservative treatment or core decompression. The latter, however, is superior to conservative treatment only in early osteonecrosis (Steinberg stage 1).²⁶ Physical therapy alone seems to be as effective as core decompression followed by physical therapy in reducing the need for total hip replacement, at least in the short term.²⁹ If a total hip replacement has become unavoidable, non-cemented hip arthroplasty, preferably with custom-made stems, is probably the best current choice.²⁷

When osteomyelitis is suspected, traditional treatment tended to include the use of ampicillin or trimethoprim-sulfamethoxazole because *Salmonella* is the main cause of this complication. However, emerging resistance is

decreasing its potential efficacy, and the spectrum of causative organisms is widening. Newer β -lactams and third-generation cephalosporins, sometimes in combination with an aminoglycoside, may be suitable alternatives.¹⁰ Quinolones are relatively contraindicated in children because of their potential for chondrotoxicity, arthropathy, and tendon rupture. Resistance to ciprofloxacin has already been described.³⁰ With established osteomyelitis, antibiotic therapy is usually continued for at least 3 months.

Septic arthritis needs early surgical drainage, antibiotics (as for osteomyelitis and guided by culture when available), débridement, and splinting to prevent ankylosis. This complication carries a poor prognosis.³¹

Recurrent gouty arthritis is treated with NSAIDs or cyclooxygenase-2-selective inhibitors and serum urate-lowering drugs such as allopurinol. Patients with SS disease and gout are likely to have renal impairment and challenged liver function. Therefore, checks of renal and liver function every 3 to 4 months are indicated.

When SS disease is associated with rheumatoid arthritis and other CTDs, the classic treatment may lead to severe and possibly life-threatening complications.³² Antiinflammatory drugs may cause acute renal failure. Corticosteroids have been associated with avascular joint necrosis, as well as with painful bony crisis with oral and intraarticular corticosteroids. There is concern regarding the use of weekly methotrexate and leflunomide. Hepatotoxicity is difficult to monitor in SS patients, who invariably have abnormal liver function. In those with active CTD, corticosteroids and methotrexate have been associated with more severe SCD-related outcomes, including more severe infections and a 20% overall patient mortality rate because of sepsis, stroke, or acute chest syndrome.³² Antimalarial therapy seems to be the least toxic disease-modifying antirheumatic drug therapy, but chronic use of such therapy is precluded by possible retinopathy. Sulfasalazine may be effective in reducing both the rheumatoid inflammation and the sickling process.³³

Tumor necrosis factor (TNF) is important in the pathophysiology of both vasoocclusive crises and rheumatoid arthritis. Experience with anti-TNF therapy and rituximab for SS disease is limited, but promising; good efficacy and tolerance are suggested in patients with SS disease and CTDs.³²

Hemochromatosis

■ ELENA M. MASSAROTTI

- Hemochromatosis refers to a general increase in body iron stores with resultant tissue damage that is most often the result of a genetically inherited defect with abnormal iron absorption caused by mutations of the *HFE* gene on chromosome 6.
- Treatment by phlebotomy can prevent organ damage but does not appear to affect hemochromatosis-related arthropathy.
- The severity of the disease varies. Asymptomatic disease, detected on routine screening demonstrating elevated iron levels, is the most common manifestation. Symmetric arthropathy may also be an early feature.
- The classic clinical picture of diabetes, bronze skin, liver disease, and arthropathy is found in only a small fraction of homozygotes.

HISTORY

The term *hemochromatosis* was first used by von Recklinghausen in 1889 for a condition initially described by Trousseau in 1865. In 1927 Sheldon¹ suggested that the disease was the result of an inborn error of metabolism. By 1955 Finch and Finch² showed that classic hemochromatosis was caused by abnormal iron absorption. These authors also confirmed that the excess iron could be removed by phlebotomy. In 1976 it was reported that the gene defect was related to HLA,³ and the mutant gene *HFE* was identified in 1996.⁴ A new diagnostic test was thus available; it replaced liver biopsy for the diagnosis of hemochromatosis and simplified family studies and screenings of populations.

GENETICS AND EPIDEMIOLOGY

Epidemiologic data for hemochromatosis are shown in Table 196.1. It was postulated that the genetic defect should be found on chromosome 6 close to the HLA locus.³ This mutant gene, *HFE*, was then identified 5 Mb distal to the HLA-A locus (Fig. 196.1).⁴ One mutation resulted in a cysteine-to-tyrosine substitution at amino acid 282, C282Y, and another caused a histidine-to-aspartic acid substitution at position 63, H63D. More than 90% of patients with hereditary hemochromatosis in northern Europe are homozygous for C282Y, and 5% are heterozygous with C282Y/H63D.¹ These compound heterozygotes have a very mild phenotypic expression.

The original mutation occurred in a person who lived in northern Europe about 2000 years ago⁵ (even if more recent studies have suggested an older age).⁶ This ancestor carried HLA-A3, and about half the descendants still carry the same conserved haplotype in linkage with the mutation (Fig. 196.2). Others carry different HLA marker haplotypes resulting from recombinations between HLA-A and *HFE*. The C282Y mutation is common (≈10%) and reaches its highest prevalence in Ireland, Brittany, the United Kingdom, Norway, Denmark, and Sweden,^{6,7} as well as in emigrants from these regions.⁸⁻¹⁰ The geographic distribution suggests early migration with the Vikings.¹¹ The prevalence declines, like that of nutritional iron deficiency of the past,^{2,11} as one travels south across Europe and is absent from the original populations of Australia, Asia, and so on.⁶ A selective advantage might explain the commonness of the mutation in former iron-deficient areas.

CLINICAL FEATURES

Hereditary hemochromatosis is an autosomal recessively inherited disease characterized by iron overload caused by abnormal iron absorption. Iron overload can also be caused by multiple blood transfusions, iron injections, and prolonged oral iron intake.¹² The classic picture of “bronze diabetes” is not a representative description of hemochromatosis today; instead, this rare manifestation should be regarded as a diagnostic failure. Some evidence suggests that earlier diagnosis and treatment have led to the perception that the frequency and extent of organ damage may be changing with time.¹³ The arthropathy associated with hemochromatosis¹⁴ is a much more common manifestation than skin pigmentation, diabetes, hypogonadism, or cardiomyopathy^{15,16} and can be the initial symptom (Fig. 196.3). Screening studies with phenotypic iron tests have shown that mildly affected cases are common,^{11,17} with observations confirmed in large genotype screenings.^{8,9} Penetrance is low, and 1 in 400 to 500 northern Europeans express the disease.

Signs and symptoms usually appear between the ages of 40 and 60 years. A rare fraction express a more “malignant” form, with the full-blown clinical picture developing at 20 years of age. This juvenile hemochromatosis is caused by mutations in the hepcidin gene (*HAMP*) on chromosome 19 or in the hemojuvelin gene (*HJV*) on chromosome 1.¹

Hemochromatosis is an “a” disorder, with asthenia, arthropathy, and alanine aminotransferase elevations being the most common manifestations.¹⁵ Asthenia, though nonspecific,⁸ paradoxically may lead to diagnosis, with iron tests being performed because of suspected iron deficiency.

Asymptomatic liver abnormalities are the most constant manifestation.^{8,9,15,18} All patients with “transaminitis” should be considered for investigation of iron overload to enable early diagnosis before the establishment of liver cirrhosis.¹⁸ Treatment started in the precirrhotic stage often results in an excellent prognosis; however, those with cirrhosis have an increased risk for the development of hepatocellular carcinoma.^{1,2}

The skin pigmentation is seldom diagnostic. Diabetes is a late and rare manifestation, like cardiomyopathy caused by iron overload. Hypogonadism with decreased libido, impotence, amenorrhea, and sparse body hair is caused by gonadotropic insufficiency and is usually a late manifestation of iron overload.

Arthropathy

Arthropathy can be the first manifestation of the iron-loading process (see Fig. 196.3), although more often it occurs later, even after treatment.¹⁴ Most joints can be affected, but osteoarthritis (OA)-like changes of the metacarpophalangeal joints of the second and third fingers are the most characteristic (Figs. 196.4 and 196.5).¹⁹⁻²¹ The disease can also affect other joints¹⁹ and may be a prominent factor affecting quality of life.²² Sometimes acute episodes of inflammatory arthritis occur as a result of deposition of calcium pyrophosphate dehydrate (Fig. 196.6).^{20,23}

The reported frequencies of arthropathy associated with hemochromatosis are variable^{12,20,22,24} and probably influenced by biased ascertainment. Its specificity has been questioned in three large screening studies using controls.^{8,9,17}

In one study of 65,238 Norwegians, 16% of men with hemochromatosis had OA as compared with 7.6% of controls.¹⁷ In a California genotype study of 41,038 individuals, self-reported arthropathy was present in 36% of C282Y homozygotes and 42.9% of C282Y/H63D heterozygotes, no different from controls at 41.6%.⁸ A genotype study of 99,711 participants in the United States and Canada gave similar results; self-reported arthritis in C282Y homozygotes was not different from controls.⁹ A small follow-up interview study²⁵ of 17 of 124 (13.7%) C282Y homozygotes from the California study⁸ seemed to indicate a higher frequency of symptoms in the

TABLE 196.1
Epidemiology of hemochromatosis

Peak age (yr)	40-60
Sex distribution (F:M)	1:4
Prevalence	10-60/10,000
Annual incidence	1-4/100,000
Geographic distribution	Most prevalent in northern European populations
Genetic associations	Most cases caused by a point mutation, C282Y, of the <i>HFE</i> gene on chromosome 6, distal to the HLA-A locus

Fig. 196.1 The ancestor's haplotype starts centromeric of the HLA-A locus and extends telomerically for more than 5 Mb, including *HFE* and its mutation C282Y (+). The ancestor probably carried A3-B7 or A3-B14.³

Fig. 196.2 Ten "unrelated" families with hereditary hemochromatosis were found to have the ancestor's HLA-A3 in common (red). A family investigation had fortunately been done and revealed that all the patients could be traced to common ancestors 11 generations earlier in the late 17th century. Homozygosity for the *HFE* mutation C282Y is marked with ++ below the individuals. Black symbols indicate affected members not available for *HFE* genotype testing. Half-filled symbols are heterozygotes (they carry only one mutation). Filled symbols indicate homozygotes or carriers of two haplotypes. Those with A3-B14 are shown in a red and those with A3-B7 in teal. (Adapted from Ritter B, Safwenberg J, Olsson KS. HLA as a marker of the hemochromatosis gene in Sweden. *Hum Genet* 1984;68:626; and Raha-Chowdhury R, Gruen JR. Localization, allelic heterogeneity and origins of the hemochromatosis gene. In: Barton JC, Edwards CQ, editors. *Hemochromatosis*. Cambridge: Cambridge University Press; 2000, p. 75-90.)

fingers and hands in C282Y homozygotes. Reviews of arthritis in hemochromatosis have been published.^{16,26}

Slight bony swelling and an inability to extend and flex the second and third metacarpophalangeal joints may be seen. Erythema or increased warmth is seldom present, the erythrocyte sedimentation rate is often normal, and rheumatoid factor is negative. Anti-citrullinated peptide antibodies were absent in the sera of patients with hereditary hemochromatosis.²⁷ Some hereditary hemochromatosis sufferers who have had arthropathy for several years have reported being reassured that "this is not rheumatoid arthritis" (RA), and the correct diagnosis was not considered.

Radiographs may show cystic lesions with sclerotic walls, joint space narrowing, sclerosis, osteophytes, and osteoporosis (see Fig. 196.5); these features are similar to those seen in idiopathic OA.^{20,28}

Although the arthropathy is most often noninflammatory, it is a prominent clinical feature that affects the quality of life of a person with hemochromatosis.²²

INVESTIGATIONS

Diagnosis of hereditary hemochromatosis is simple, provided that it is considered. The screening tests are transferrin saturation, expressed as the serum iron concentration divided by the iron-binding capacity multiplied by 100, which is elevated (>45%), in combination with an increased serum ferritin concentration (>200 µg/L in males, >100 µg/L in females). If an inflammatory condition is superimposed, percent transferrin saturation drops (Fig. 196.7). If the screening test results are abnormal, they should be followed by the *HFE* genotype test. A finding of homozygosity for C282Y or compound heterozygosity for the two mutations C282Y/H63D confirms the diagnosis. If the liver test results are abnormal and serum ferritin signals severe iron overload (>1000 µg/L), liver biopsy is recommended.¹ Once the diagnosis is established, all first-degree relatives should be screened with genotype and iron tests.¹ Population screening is no longer recommended because of the low penetrance of the genotype.^{1,8,9}

DIFFERENTIAL DIAGNOSIS

Secondary iron overload, which sometimes produces arthropathy, is excluded by a history that does not include blood transfusions, parenteral

Fig. 196.3 A record from 1936 showed that the father (VIII:3 on Fig. 196.2) had suffered from "polyarthritis" from the age of 48. He died at 49 years of "diabetes bronze and myocarditis" proven by autopsy. Fifty years later, arthropathy developed in his eldest daughter and she underwent total hip replacement. Child No. 4, a son, died of a hepatoma. Child No. 7, the youngest son, has had arthropathy from the age of 26, abdominal pain from the age of 30, a diagnosis of "seronegative polyarthritis" at age 39, hypogonadism at age 44, and the diagnosis of "hemochromatosis with cirrhosis" at age 46. Children Nos. 3, 5, and 6 were mainly free of symptoms despite being homozygous. (Adapted from Ritter B, Safwenberg J, Olsson KS. HLA as a marker of the hemochromatosis gene in Sweden. *Hum Genet* 1984;68:626.)

Fig. 196.4 The hands of a patient with hemochromatosis. The bony swelling of the metacarpophalangeal joints is apparent.

Fig. 196.5 Radiograph of the hand of a 45-year-old man with hemochromatosis. Cystic lesions of the metacarpal heads, joint space narrowing, and osteophytes at the second and third metacarpophalangeal joints are present.

Fig. 196.6 Findings from a broad biochemical laboratory profile show constantly abnormal transferrin saturation and elevated transaminase levels in a 44-year-old man with pseudogout as the initial symptom. Liver biopsy confirmed the diagnosis of hemochromatosis in the cirrhotic stage. The effect of phlebotomy is obvious. ALT, alanine aminotransferase; AST, aspartate aminotransferase; Hb, hemoglobin; TIBC, total iron-binding capacity.

CHANGES IN TRANSFERRIN SATURATION INDUCED BY AN INFLAMMATORY REACTION

Fig. 196.7 The patient, aged 69, suffered a myocardial infarction on day 4 (arrow) while hospitalized because of hemochromatosis. The remarkable drop in plasma iron is probably an effect of increased hepcidin activity.^{1,24}

iron administration, and anemia (β -thalassemia, sideroblastic anemia). Porphyria cutanea tarda is also manifested as elevated percent transferrin saturation, increased serum ferritin concentration, and abnormal liver test results. However, these patients have more intense pigmentation, skin fragility, blisters, and hirsutism.¹ Interestingly, the C282Y mutation has been found in 40% of patients with porphyria cutanea tarda.²⁹

Alcoholic liver disease might be associated with an increased serum ferritin concentration and elevated transferrin saturation. Abstinence often results in a rapid drop in these parameters.

PATHOGENESIS

In hemochromatosis, absorption of iron from the diet is increased. Because iron excretion is minimal, the result is progressive iron loading of parenchymal tissues, particularly the liver.¹ Studies have identified several new genes along the iron pathway through the major cell types involved (Fig. 196.8).³⁰ The iron hormone hepcidin has a central role in regulating the influx of iron into plasma from red cell breakdown in macrophages and iron-absorbing gut cells. With low hepcidin expression, plasma iron increases as in hemochromatosis. When inflammation takes place, hepcidin activity increases and plasma iron is reduced (see Fig. 196.7). Hemochromatosis thus seems to be the opposite condition of anemia of chronic disease. How the defective C282Y protein interacts with hepcidin is not yet clear.

Within the cell, extra iron is stored in lysosomes as ferritin and hemosiderin. Iron may be toxic to the cell by inducing free radical production, which causes lipid peroxidation and weakening of lysosomal membranes. An iron load of no more than 3 g (only four times normal) can induce liver cells to release transaminases.¹⁸ Knowledge of the joint pathology seen in hemochromatosis has been derived largely from joint replacement surgery.¹⁶ In contradistinction to secondary hemochromatosis, in which iron deposition is noted in the sublining areas of the synovium or synovial stroma, iron deposition in primary hemochromatosis occurs in the synovial lining cells.^{16,31} The histopathology of hemochromatosis-

IRON DELIVERY TO PLASMA FROM THE ENTEROCYTE AND THE MACROPHAGE IS REGULATED BY THE IRON HORMONE HEPcidIN PRODUCED BY THE HEPATOCYTE

Fig. 196.8 When the hepcidin activity is inappropriately low, plasma iron increases as in hemochromatosis. The opposite situation is seen with inflammation (see Fig. 196.6) and the anemia of chronic disease. (From Fleming RE, Bacon BR. Orchestration of iron homeostasis. *N Engl J Med* 2005;352:1741-4.)

related arthropathy lies between that of OA and RA.^{27,32} Synovial infiltration of macrophages and neutrophils is more pronounced in hemochromatosis than in OA. Hemosiderin deposition is not found in RA or OA but can be found in hemochromatosis-related arthropathy. However, B and T cells, which are present in RA synovium, are not seen in hemochromatosis-related arthropathy. No clear relationship has been found between iron load and effect on the synovium.^{19,20,32} Biopsy specimens have demonstrated hemosiderin granules in type B synovial cells rather than in macrophage-like type A cells, as seen in RA and hemarthrosis. Synovial inflammation is scarce.¹⁴ Ferritin particles have been identified in intact chondrocytes together with calcium pyrophosphate dehydrate crystals in cartilage.³² The osteoporosis associated with hemochromatosis is usually a late manifestation.

Environmental factors

Several factors other than age can influence phenotypic expression of the disease, such as blood donation and menstrual blood loss. Dietary factors, such as high intake of dairy products, may explain why patients in Scandinavia with hereditary hemochromatosis are less iron loaded than their genetic relatives living in Germany, Australia, or other, more fertile areas.^{15,19,22} Excessive alcohol intake has an additive influence on the liver damage, and iron tablets may worsen the phenotype.

MANAGEMENT

Excess iron is removed from the body by weekly phlebotomy. Each unit of blood (450 cm³) contains 200 to 250 mg of iron, and this quantity is mobilized from storage sites to compensate for the blood loss. Bloodletting is well tolerated and is continued until the serum ferritin level indicates iron depletion (30 to 40 mg/L). Maintenance phlebotomy three to six times a year is then required to prevent iron reaccumulation. Dietary restrictions are not needed. Liver function improves during phlebotomy (see Fig. 196.6), the abdominal pain disappears, and general well-being is increased. Even the cardiomyopathy is reversible, but diabetes and hypogonadism are not usually affected by iron removal.

Arthropathy does not generally improve with phlebotomy.¹⁹ Treatment with nonsteroidal antiinflammatory drugs is helpful in the majority of patients.

METABOLIC BONE DISEASE

197

Epidemiology and classification of osteoporosis

■ CHRISTOPHER HOLROYD ■ ELAINE DENNISON ■ CYRUS COOPER

- Osteoporosis is a systematic skeletal disorder characterized by low bone mass, microarchitectural deterioration of bone tissue, and susceptibility to fracture. It can be divided into primary and secondary forms.
- The most widely used definition of osteoporosis is that of the World Health Organization: bone mineral density (BMD) greater than 2.5 standard deviations or greater below the young normal mean.
- Even though BMD and bone strength are strongly correlated, other factors may weaken bone independently of BMD; hence, there has recently been a move toward assessing an individual's 5- or 10-year risk for osteoporotic fracture. An example of such a model is the FRAX tool.
- Risk factors for low BMD relate to either inadequate bone formation during growth or excessive bone loss thereafter, but the underlying pathogenesis remains somewhat obscure.
- Fractures, the clinical manifestation of osteoporosis, increase dramatically with aging and are more frequent in women than in men and in whites than in other races.
- Hip fractures are most devastating in terms of mortality, morbidity, and cost, but other types of fracture contribute substantially to the social burden of osteoporosis.
- Because of the dramatic growth in the elderly population worldwide, the number of osteoporotic fractures will increase substantially in future years unless cost-effective control programs can be implemented.

INTRODUCTION

Osteoporosis is a systematic skeletal disorder characterized by low bone mass and microarchitectural deterioration of bone tissue that increases the fragility of bone and hence susceptibility to fracture. It is increasingly being recognized as a global concern and remains the most common metabolic bone disease; osteoporosis affects both sexes and all races. Osteoporotic fractures are not only common but may also have devastating consequences. They represent a major public health problem because they increase patient morbidity and certain fractures (e.g., hip and vertebral fractures) are associated with increased mortality. The public health burden of the disease is likely to rise in future generations, in part because of an increase in life expectancy and a growing elderly population. Understanding the epidemiology of the disease is crucial in trying to develop strategies to help reduce this load.

HISTORY

Historically, the term *osteoporosis* first entered medical terminology in France in the 19th century. Jean Lobstein, a French pathologist, used the

term to emphasize the porosity of the histologic appearance of aged human bone (porosis = porous bone). Around the same time, Sir Astley Cooper, an English surgeon, suggested that certain types of fractures may occur as a result of the age-related reduction in bone mass or quality.¹ He described the classic epidemiologic hallmarks of these fractures: incidence rates that increase with age, rates that are higher in women than in men, and fractures that are associated with only moderate trauma at sites containing large amounts of trabecular bone. Little attention was paid to the disease until the 1940s, when Fuller Albright, an American endocrinologist, attributed the disease to loss of estrogen after menopause. Unfortunately, at that time a reliable test for the diagnosis of osteoporosis was not available, so most patients came to medical attention only after a fracture. It was not until the 1960s, with the introduction of bone densitometry, that greater understanding of the association between osteoporosis and certain fractures was achieved and the potential public health burden of the condition became apparent. Since the 1980s, much progress has been made in terms of therapeutic developments for prevention of osteoporosis with the introduction of bisphosphonates and other agents.

OSTEOPOROSIS

Definition

The definition of osteoporosis remains difficult. Dual-energy x-ray absorptiometry is currently the "gold standard" tool for measuring bone mass, and from this, bone mineral density (BMD) can be obtained. BMD and the strength at which bones break *in vitro* are strongly correlated; however, BMD does not completely explain the architectural changes in bone that lead to skeletal fragility. Nonetheless, it is recognized that BMD is highly predictive of fracture risk. In 1994, an expert panel convened by the World Health Organization (WHO) established the most widely used definition that encompasses both BMD and previous fracture.² They defined osteoporosis as a state in which BMD in women falls more than 2.5 standard deviations below the young adult mean. This definition, however, takes into account only deterioration in bone mineralization and does not consider any of the microarchitectural changes that may weaken bone independently of any effect on BMD. More recently, there has been a move toward assessing an individual's absolute risk for osteoporotic fracture, an example of which is the FRAX tool.³

Classification

Osteoporosis can develop as a primary disorder or be secondary to other factors such as associated medical diseases, surgical procedures, or medications known to accelerate bone loss. It is important to note that both categories are not completely independent of each other and may on occasion be additive; for example, in individuals with primary osteoporosis, secondary causes may further aggravate the bone loss and increase the risk for fractures.

BOX 197.1 SECONDARY CAUSES OF OSTEOPOROSIS

- Immobilization
- Malignancy
- Chronic renal failure
- Gastrointestinal disease:
 - Malabsorption syndrome
 - Liver disease
 - Inflammatory bowel disease
- Rheumatologic disease:
 - Rheumatoid arthritis
 - Systemic lupus erythematosus
- Genetic conditions:
 - Cystic fibrosis
 - Osteogenesis imperfecta
 - Ehlers-Danlos syndrome
 - Glycogen storage diseases
 - Prolonged weightlessness
- Chronic obstructive pulmonary disease
- Endocrine disease:
 - Cushing disease
 - Hyperparathyroidism
 - Hyperthyroidism
 - Hypogonadism
 - Hyperprolactinemia
 - Diabetes mellitus (type 1)
- Drugs:
 - Corticosteroids
 - Ethanol
 - Antiepileptics
 - Heparin
 - Tobacco

Primary osteoporosis accounts for more than 95% of cases of osteoporosis in women and 70% to 80% in men. In general, it occurs in postmenopausal women and older men. *Idiopathic osteoporosis* is included in this category and is used to describe the uncommon forms of osteoporosis found in children and young adults with normal gonadal function and no detectable secondary cause. The pathogenesis of this type remains unclear. *Secondary osteoporosis* accounts for less than 5% of cases of osteoporosis in women but up to 20% in men. Its causes are listed in Box 197.1.

Assessment of fracture risk

Since 1994, osteoporosis has been defined in terms of BMD. In general, clinical development of pharmacologic agents has focused on the selection of patients on the basis of low BMD with or without prevalent vertebral deformities for inclusion into trials of efficacy. Thus guidance on whom to treat has emphasized assessment of BMD. Use of T-scores has many benefits because it is simple and widely used, is strongly correlated with risk for fractures, and can detect some high-risk patients.² However, shortcomings include lack of standardization regarding which skeletal sites to study, lack of generalization to the nonwhite population, and the fact that it evaluates BMD as the only risk factor for fracture.

Given the increasing evidence now suggesting that T-scores alone are insufficient predictors of fracture risk, the WHO convened a scientific group to develop more accurate ways of assessing fracture risk. The use of clinical risk factors together with age and BMD increases the sensitivity of fracture prediction still further without sacrificing specificity. From this, multivariate models have been created that allow the 10-year probability of hip and other fractures to be predicted. An example of such a model is the FRAX tool³ developed in the United Kingdom by the WHO. Clinicians can easily input clinical data to estimate the 10-year probability of hip and major osteoporotic fractures (which includes forearm, hip, spine, and humerus fractures) in men and women between 40 and 90 years of age. The estimate can be used alone or with BMD to enhance fracture risk prediction. The 10-year probability of fracture was preferred over lifetime risk for several reasons, namely, treatments are not given for a lifetime, the 10-year interval accommodates the clinical trial experience of interventions, and the long-term prognostic value of some risk factors may decrease with time. If an individual's life expectancy is less than 10 years, the probability produced by FRAX equals the remaining lifetime risk for fracture. In addition, the FRAX tool does not simply adjust for mortality risk based on average mortality rates for the population but also accommodates for the fact that many risk factors that predict fracture risk also influence mortality (older age, previous fracture, low body index, smoking).

Using cost-effectiveness analysis, intervention thresholds for use in clinical practice within the United Kingdom concerning when to commence treatment (or perform BMD testing if not yet done) have also been added to the model. These thresholds are in accordance with recent U.K. National Osteoporosis Guideline Group guidance and are set by age and sex and based on a fracture probability equivalent to that of women with a history of a previous osteoporotic fracture. For example, the intervention threshold for treatment at the age of 50 years corresponds to a 7.5% 10-year probability of sustaining a major osteoporotic fracture. This figure rises progressively with age to 30% at the age of 80 years; assessment thresholds for BMD

CHANGES IN BONE MASS OVER TIME IN WOMEN AND MEN

Fig. 197.1 Changes in bone mass over time in women and men.

testing also rise with age (6% to 9% at 50 years rising to 18% to 36% at the age of 80 years).⁴

The FRAX model has now been calibrated to the epidemiology of 44 other countries. It is important to note that any intervention thresholds developed in one country may not be applicable to other countries. For instance, intervention thresholds have also been developed in the United States by the National Osteoporosis Foundation and suggest that persons with a 10-year risk for major osteoporotic fracture of 20% or higher or a 10-year risk for hip fracture of 3% or higher should receive pharmacologic treatment to reduce this risk.

Risk factors

Constitutional and lifestyle risk factors for low BMD are numerous, although none have high enough sensitivity to confirm or exclude the diagnosis of osteoporosis. Factors that influence BMD exert their effect in two ways—through either inadequate development of peak bone mass or an excessive rate of bone loss (or a combination of the two). Genetic factors are thought to be very important in the attainment of peak bone mass; family studies have examined parent-offspring and sibling-sibling correlations in BMD and found correlation coefficients of 0.28 to 0.59,^{5,6} and twin studies have shown much closer concordance of bone density in monozygotic than in dizygotic twins.⁷ However, environmental factors such as hormonal status, physical activity, and calcium intake are also important in attaining peak bone mass. Environmental influences are thought to be more important than genetic factors in determination of bone loss.

Increasing age is an important risk factor for osteoporosis. Peak bone mass is achieved in men and women by the mid-20s. It then plateaus for around 10 years before falling at a rate of 0.3% to 0.5% each year. At menopause the rate of bone loss in women accelerates to around 3% to 5% per year for 5 to 7 years before returning to the previous rate of decline (Fig. 197.1). This accounts for the increasing incidence of osteoporosis with age. Female gender is also important; men naturally have higher bone mass than women and do not have an accelerated rate of bone loss corresponding to that in women around menopause. Other risk factors include low body weight and weight loss, late age at menarche, early age at menopause, physical inactivity, low dietary calcium intake, smoking, and increased alcohol and caffeine intake. A previous fracture and a maternal history of fracture are further risk factors. In individuals with a maternal history of fracture, the risk for hip fracture is doubled.⁸ Protective factors for osteoporosis include greater height, weight, and muscle strength; increased dietary calcium; greater physical activity; later age at menopause; and postmenopausal estrogen use.

Prevalence and incidence

The prevalence of osteoporosis in the European Union in 2010 was estimated to be 27.6 million. Furthermore, it has been estimated that 10 million Americans older than 50 years have osteoporosis and that a further 34 million are at risk for the disease. This figure is likely to increase to more than 14 million in 2020.⁹ Epidemiologic studies from North America have

estimated that the remaining lifetime risk for an osteoporotic fracture is 40% in white women 50 years of age (Table 197.1); the risks are 17.5% for hip fracture, 15.6% for clinically diagnosed vertebral fracture, and 16% for distal forearm fracture. Corresponding risks in men are 6%, 5%, and 2.5% (13.1% overall risk for osteoporotic fracture). Data from the General Practice Research Database in the United Kingdom (which includes 6% of the U.K. population)¹⁰ have indicated that the risk is similar in the United Kingdom. In women, the 10-year risk for any fracture increases from 9.8% at 50 years of age to 21.7% at 80 years, whereas in men the 10-year risk remains fairly stable with advancing age (Table 197.2). Our knowledge of the epidemiology of childhood fractures in the United Kingdom has recently been expanded by interrogation of the same database; at their childhood peak, the incidence of fractures (boys, 3%; girls, 1.5%) is surpassed only at 85 years of age in women and never in men (Fig. 197.2).

Health impact of osteoporotic fracture

All osteoporotic fractures are associated with significant morbidity, but both hip and vertebral fractures are also associated with excess mortality. It has been estimated that around 740,000 deaths take place per year worldwide as a result of hip fracture, with 21,000 occurring in the European Union within the first year of fracture. Worldwide, osteoporotic fractures account for 0.83% of the global burden of noncommunicable disease and 1.75% in Europe, where osteoporotic fractures account for more disability-adjusted life years than many other chronic noncommunicable diseases do.¹¹

Mortality

There is clear evidence of excess mortality associated with hip and vertebral fracture in both sexes. It has been estimated that only 25% of deaths from hip fracture are due to the fracture itself or to complications such

as infection, thromboembolism, and subsequent surgery.¹² The rest of the mortality reflects coexisting morbidity from underlying disease. In individuals sustaining a vertebral fracture, these comorbid conditions probably play an even larger role in mortality rates. Fractures of the forearm tend to not be associated with increased mortality except in elderly men, in whom slightly excess mortality has been observed.

It has been estimated that 8% of men and 3% of women older than 50 years die while hospitalized for their hip fracture. Mortality rates after hip fracture continue to rise over the subsequent months and peak at 1 year, with a rate of 36% for men and 21% for women.¹³ Mortality rates then tend to decline after the first year. Recent data from the Dubbo Epidemiology Study of community-dwelling women and men 60 years and older suggest that the elevated mortality persists for up to 10 years for hip fracture.¹⁴

After a vertebral fracture the excess mortality appears to remain in effect for up to 5 years in both sexes.¹⁴ This has been observed both in studies using clinically diagnosed vertebral fractures and in those using radiologic morphometric approaches to classify vertebral deformity. Impaired survival is more pronounced for vertebral fractures that follow moderate trauma rather than severe trauma, only 8% of which are actually attributable to osteoporosis. Five-year survival appears to be worse for men (5-year survival rate of 72%) than for women (5-year survival rate of 84%). In women, as the number of vertebral fractures increases, increased risk for death from cardiovascular and pulmonary disease has been observed.¹⁵

Overall, the four main predictors of higher mortality after fragility fractures appear to be male sex, increasing age, coexisting illness, and poor prefracture functional status. Smoking and low BMD may also be predictors in women.¹⁴

Morbidity

In 2004 a Swedish study weighted osteoporotic fractures according to morbidity (in terms of cumulative loss of quality of life) in an attempt to obtain an accurate determination of the true burden of osteoporotic fracture.¹⁶ Thus for a man between 50 and 54 years of age the disability caused by osteoporotic fractures is 4.5 times that accounted for by hip fracture alone; for women of the same age, the disability caused by osteoporotic fractures is 6 times that accounted for by hip fractures alone. The cumulative loss of quality of life tends to decrease with age. Four vertebral fractures appear to have the same morbidity as one hip fracture.

In the United States, about 7% of survivors of all types of fragility fractures have a degree of permanent disability and 8% require long-term nursing home care. Overall, after any type of fracture, a 50-year old white American woman has a 13% chance of experiencing attributable functional decline.¹⁷ Hip fracture invariably requires hospitalization, and patients are susceptible to the development of acute complications such as pressure sores, bronchopneumonia, and urinary tract infections. The degree of functional recovery after hip fracture depends on age. Recent data from the multinational Global Longitudinal Study of Osteoporosis in Women

(GLOW) cohort showed that 134 patients who sustained a hip fracture over the 1-year follow-up accounted for 1306 days of hospitalization and 1650 days of rehabilitation or nursing home care.¹⁸

Hip fracture has a significant effect on an individual's ability to walk; 40% are still unable to walk independently 1 year after hip fracture, with 60% requiring assistance in at least one essential activity of daily living (e.g., dressing, bathing); 80% are unable to perform at least one instrumental activity of daily living, such as driving or shopping.¹³

Despite only a minority of vertebral fractures coming to clinical attention, they account for around 52,000 hospital admissions in the United States and more than 2000 in England and Wales each year in patients 45 years or older. The impact of a single vertebral fracture can often be low, but multiple fractures lead to progressive loss of height and kyphosis and severe back pain in both the acute and chronic stages.¹⁵ The resultant loss of mobility can further exacerbate the underlying osteoporosis and lead to an increased risk for further fractures.¹⁶ The psychological impact of functional loss can result in depression and social isolation, as well as loss of self-esteem. Participants in the European Prospective Osteoporosis Study (EPOS) with a radiologically identified vertebral fracture at baseline had radiographs repeated 3 years later. Women who had suffered a further fracture during this period experienced substantial levels of disability along with impairment in key physical functions of independent living.¹⁹

Wrist fractures do not seem to increase mortality. They may have an impact on some activities such as writing or meal preparation, but few patients are completely disabled. More than 50%, however, still report only fair to poor function at 6 months, often because of complications such as reflex sympathetic dystrophy, neuropathy, and posttraumatic arthritis.¹⁵

Bone mineral density and fracture

Several prospective epidemiologic studies have shown that BMD is a strong predictor of fracture independent of age. Risk for osteoporotic fracture increases continuously as BMD declines, with a 1.5- to 3-fold increase in risk for fracture for each standard deviation fall in BMD.² There is no convincing evidence of a threshold in the relationship between BMD and fracture; the relationship appears to be continuous. In the Rotterdam study, a prospective population-based cohort study of 7806 men and women 55 years or older, the age-adjusted hazard ratio for all nonvertebral fractures per standard deviation decrease in femoral neck BMD was 1.5 for women and 1.4 for men.²⁰ For hip fractures, hazard ratios were 2.1 for women and 2.3 for men. A meta-analysis of prospective studies from 1996 found that for each standard deviation decrease in hip BMD, the risk for hip fracture increases by 2.6-fold.²¹

Some evidence also suggests a definite inverse correlation between BMD and the severity of fracture. Recent data from the United Kingdom on distal radial fractures revealed an increased rate of early instability, malunion, and carpal malalignment after fractures in patients with reduced BMD.²²

Although it has its limitations, measurement of bone density is currently the best available method of predicting future fracture. Appropriate cutoff

values have been defined by the WHO so that intervention can be directed toward "at-risk" individuals (Table 197.3). The relationship between BMD and osteoporosis can be compared with that between blood pressure and stroke. Although hypertension is a risk factor for stroke, stroke can occur in individuals with normal blood pressure. Likewise, fractures can occur in the absence of osteoporosis. Of note in the Rotterdam study, only 44% of nonvertebral fractures occurred in women with a T-score lower than -2.5 (the WHO definition of osteoporosis); in men this percentage was even lower at 21%. This highlights the presence of other known risk factors for fracture that are independent of BMD: family history of fracture, cigarette smoking, excess alcohol consumption, and low body weight. Thus BMD alone cannot reliably discriminate between individuals who will sustain a fracture and those who will not.

FRACTURE EPIDEMIOLOGY

It is estimated that 3.5 million fragility fractures occur every year in the European Union.²³ Fracture incidence in the community is bimodal, with a peak in the young and in the elderly. In young people, fractures are usually associated with substantial trauma, occur in the long bones, and are seen more frequently in males than in females. In this group the question of bone strength rarely arises. Osteoporotic fractures characteristically occur in areas of the skeleton with a high amount of trabecular bone after low or moderate trauma. The "classic" osteoporotic fragility fractures are hip, vertebral, and wrist fractures, although prospective studies have shown increased risk for almost any type of fracture. The frequency of fracture increases with age in both sexes because of a combination of lower bone density and the increased tendency to fall in the elderly (Fig. 197.3).

TABLE 197.3
Diagnostic categories for osteoporosis based on World Health Organization criteria

Category	Definition
Normal	BMD not more than 1 SD below the young adult mean value
Low bone mass (osteopenia)	BMD lying between 1 and 2.5 SD below the young adult mean value
Osteoporosis	BMD more than 2.5 SD below the young adult mean value

BMD, bone mineral density; SD, standard deviation.

Fig. 197.3 Age-specific incidence of common fractures in men and women. (Modified from Sambrook P, Cooper C. Osteoporosis. Lancet 2006;367:2010-18.)

Hip fracture

Hip fracture is the most devastating consequence of osteoporosis. It has been estimated that worldwide, around 1.7 million hip fractures occurred in 2000, 1,197,000 in females and 463,000 in males.²⁴ In individuals older than 50 years in Western populations, there is a female preponderance of hip fracture with a female-to-male incidence ratio of approximately 2:1. Overall, 90% of hip fractures occur in people older than 50 years, and 80% occur in women (because there are more elderly women than men).²⁵ Hip fractures are seasonal, with an increase in winter in countries in a temperate climate. They occur mainly indoors, thus suggesting that the increase is not caused by slipping on icy pavement. It may be related to slowed neuromuscular reflexes and lower sunlight in winter, as well as to seasonal changes in vitamin D levels and bone turnover.

Incidence rates of hip fracture vary considerably; in general, individuals who live in latitudes farther from the equator have a higher incidence of fractures, as do those who live in urban rather than rural areas. Racial differences have clearly been observed, with lower fracture rates in black than in white or Asian populations. Incidence rates also vary considerably according to geographic area (Table 197.4) and may differ widely even within the same country in populations of a given sex and race. In a study of the 10-year probability of hip fracture standardized for gender and age across 29 countries, a greater than 10-fold variation in risk for hip fracture between countries was observed, with the highest rates in Scandinavia and low rates in Africa and South America.²⁶ Figure 197.4 illustrates the variation in hip fracture incidence throughout the world.

In Europe, hip fracture rates vary sevenfold between northern and southern countries. The highest rates of hip fracture are seen in whites living in northern Europe, especially Scandinavians. A recent systematic review of hip fractures worldwide found the highest rates in Denmark (574/100,000),

closely followed by Norway (563/100,000) and Sweden (539/100,000).²⁶ The rates are intermediate in people from China, and Kuwait and lowest in black populations.²⁷ Data from Middle Eastern and African countries are limited because of the absence of fracture registries. A study of hip fractures in Morocco suggested that fragility fractures occur in North Africa less frequently than in most European, North American, and Asian countries but more frequently than in sub-Saharan African countries.²⁸ Many of the lower incidence rates seen in these developing countries can be partially explained by lower life expectancy in Latin America, with only 5.7% of the population being older than 65.

It is likely that the differences in hip fracture rates are a combination of genetic and environmental factors. However, the factors studied thus far, such as alcohol consumption, smoking, activity levels, obesity, and migration status, have not explained these trends. The differences may be related to differences in risk for falling because BMD measurements are similar in white and nonwhite women and men after correction for bone size. Further research is clearly needed to explain these important environmental factors.

Secular trends in hip fracture

Trends in hip fracture rates over time in many countries have also been reported. From the 1930s until the mid-1980s, age- and sex-specific hip fracture incidence rates rose across the United Kingdom and Scandinavia. In the United States, data from Rochester, Minnesota, showed a similar trend in age-adjusted rates for men, whereas in women the rate increased until the 1960s and then plateaued until the 1980s.²⁹ Since then the age-adjusted incidence rate of hip fracture has fallen across most of northern Europe and North America, more than counteracting the effects of the aging population and resulting in a decline in the annual number of hip fractures. This phenomenon may reflect the implementation of osteoporosis screening and treatment programs, among other factors. In the United Kingdom the rate fell by 0.5% between the years 1992 and 1998,³⁰ and in the United States the rate fell by 1.4% over the years 1980 to 2006.³¹ The rate in southern Europe and parts of Asia continues to rise, however, with observed increases of 3% and 3.8% in age-adjusted hip fracture incidence rates in Spain and Japan, respectively (Fig. 197.5). These discrepancies in secular trends by race, gender, and age are likely to represent a combination of genetic and environmental factors. Many of these factors remain poorly elucidated, but with improved understanding it is hoped that novel public health measure may be identified. The relationship between socioeconomic status and fracture risk remains unclear, although a recent systematic review has suggested that BMD in women is positively associated with educational attainment.³²

Vertebral fracture

Only a fourth of vertebral fractures result from falls, and most are precipitated by routine daily activities such as bending or lifting light objects. Until recently, accurate epidemiologic studies of vertebral fracture had been limited, partly because of the often asymptomatic nature of the fracture, as well as a lack of consensus regarding the techniques that should be used to define vertebral deformity. However, the advent of morphometric and semi-quantitative visual techniques has now enabled a number of studies to report on the prevalence of vertebral fractures. Only about a third of all vertebral deformities noted on radiographs come to medical attention, and less than 10% necessitate admission to a hospital.³³ Data from the United States (Rochester, Minnesota) suggest that the prevalence of any vertebral

Fig. 197.4 Categorization of hip fracture rates for women in different countries by risk. deformity is 25.3% per 100 women 50 years and older, and the incidence of a new deformity in this group is estimated to be 17.8 per thousand person-years.³⁴ By contrast, in the European Vertebral Osteoporosis Study, one in eight women and men 50 years and older had evidence of a vertebral deformity.³⁵ The prevalence of vertebral deformity increased steadily with age in both sexes, although the gradient was steeper for women. There is a threefold variation in the occurrence of deformity across Europe and up to a twofold variation in centers within individual countries, perhaps reflecting a combination of environmental and genetic factors. The risk for vertebral deformity in men was significantly elevated in those with high levels of physical activity, thus suggesting the importance of trauma (possibly occupational) as a cause. By contrast, women with higher levels of customary physical activity may have a reduced risk for deformity.³⁶

The prevalence of vertebral fractures varies less across regions than the prevalence of hip fractures does. For example, the risk for vertebral fractures in postmenopausal women in Beijing is only 25% lower than that in women in the United States despite much lower hip fracture rates in the former.³⁷ Recent data from the EPIDOS (Epidémiologie de l'Ostéoporose) study have yielded estimates of the prevalence of vertebral fractures: 19% of women aged 75 to 79 years, 21.9% of women aged 80 to 84 years, and 41.4% of those 85 years and older would be expected to sustain a vertebral fracture. These observations are broadly in keeping with estimates from other populations.³⁸

Wrist fracture

Distal forearm fracture almost always results as a consequence of a fall from standing height onto an outstretched hand. These fractures show a steep rise in incidence during the perimenopausal period in women but tend to plateau thereafter. In men, the incidence remains constant between 20 and 80 years of age. A much stronger sex ratio exists for this fracture than for most others, and it has been estimated to be 4:1 in favor of women. Recent data from Dorset in the United Kingdom showed that in women, the incidence of distal radius fracture rose from a premenopausal baseline of 10 per 10,000 of the population per year to a peak of 120 per 10,000 of the population per year older than 85 years.³⁹ Although geographic variation exists, a

partial explanation may be methodologic considerations of case ascertainment because less than 20% of patients with a forearm fracture are hospitalized. A winter peak is again demonstrated, but unlike hip fractures, this peak is probably due to falls outside on icy surfaces. The plateau with age in women may be due to the mode of falls because later in life a woman is more likely to fall onto a hip than onto an outstretched hand because of deterioration in neuromuscular coordination.

Clustering of fractures

Several epidemiologic studies have shown that patients with fragility fractures are at increased risk for the development of additional osteoporotic fractures, both at the same site and at other locations. In general, the presence of previous vertebral deformities has been shown to increase the risk for subsequent vertebral deformities by 7- to 10-fold.⁴⁰ This is comparable to the increase in risk for a second hip fracture observed in those who have already sustained a first hip fracture. In a retrospective cohort study of 1288 residents of Rochester, Minnesota, a distal forearm fracture occurring when 35 years or older was associated with a 1.4-fold increased risk for subsequent hip fracture in women (95% confidence interval [CI], 1.1 to 1.8) and a 2.7-fold increased risk for hip fracture in men (95% CI, 0.98 to 5.8).⁴¹ Excess risk in women was confined to individuals who sustained their first forearm fracture at 70 years or older. By contrast, a previous distal forearm fracture increased the risk for vertebral fracture across all ages, with a 5.2-fold (95% CI, 4.5 to 5.9) increased risk in women and a 10.7-fold (95% CI, 6.7 to 16.3) increased risk in men. This increased risk was more marked in subjects with vertebral deformities associated with moderate or minimal trauma than with severe trauma.

Regarding vertebral fracture data from EPOS,⁴⁰ prevalent vertebral deformity was seen to predict incident hip fracture at a rate ratio of 2.8 to 4.5, and this figure increases with the number of vertebral deformities. In the United States, data from the Study of Osteoporotic Fractures (a prospective study of 9704 U.S. women 65 years or older) demonstrated that prevalent vertebral deformity was associated with a 5-fold increased risk for sustaining a further vertebral deformity; the risk for hip fracture was increased 2.8-fold (95% CI, 2.3 to 3.4) and the risk for any nonvertebral fracture was increased

1.9-fold (95% CI, 1.7 to 2.1) after adjustment for age and calcaneal BMD.⁴² Despite a small increased risk for wrist fracture, it was not significant after adjustment for age and BMD. In the United Kingdom, a study has recently shown that 25% of patients with a new low-trauma nonvertebral fracture had evidence of a previous vertebral fracture.⁴³ The greatest risk for a subsequent fracture appears to occur soon after a fracture, particularly in the first year, with the incidence of a new vertebral fracture being 19.2%.⁴⁴ This increased risk for virtually all clinical fractures may persist for up to 10 years.⁴⁵

Some evidence suggests that individuals 50 years or older who sustain a rib fracture (as recalled from memory) have an increased risk for future limb fracture. The predictive risk was particularly marked for subsequent hip fracture (relative hazard [RH], 7.7; 95% CI, 2.5 to 25.9) and humerus fracture (RH, 4.5; 95% CI, 1.4 to 14.6).⁴⁶

Economic cost

The first-year direct cost per hip fracture in the United Kingdom was recently estimated to be between €11,055 and €20,359.⁴⁷ Worldwide, the combined direct and indirect annual costs for hip fracture have been predicted to rise to US \$131.5 billion by 2050 (at a cost of \$21,000 per patient).⁴⁸ A recent analysis estimated that patients with osteoporosis-related fractures incurred nearly US \$10,000 in excess direct health care costs in the 6 months after fracture when compared with patients with no fracture.⁴⁹ The costs associated with other fractures have also recently been calculated. In the United States, the cost of osteoporotic fractures in 2005 was estimated to be \$19 billion.⁵⁰ More recently, the cost of osteoporosis, including pharmacologic intervention in the European Union, was estimated to be €37 billion²³; in the United Kingdom alone the annual cost to the health care system for osteoporotic fractures was €5.5 billion.⁴⁷ Hip fractures account for more than a third of the total figure. Expenditures are rising faster than the general rate of inflation and are a major source of concern to governmental leaders. Much research is currently focusing on the cost-effectiveness of treatment programs for osteoporosis. At present this still remains difficult to assess, and in addition, the widespread use of expensive drugs may not be affordable in many countries. The cost of various fractures in the United Kingdom is illustrated in Table 197.5.

FUTURE PROJECTIONS

Osteoporotic fractures represent a significant public health burden that will rise in future generations because of an aging population. Life expectancy is increasing around the globe, and the number of elderly individuals is rising within every geographic region. The world population is expected to increase from the current 323 million individuals 65 years or older to more than 1.5 billion by the year 2050. These demographic changes alone can be expected to increase the number of hip fractures occurring worldwide. The

TABLE 197.5
First-year costs of osteoporotic fracture in the United Kingdom

Site	Cost (€)
Hip (first year)	11,055
Forearm	1,263
Clinical vertebral fracture	2,756
Other fractures	7,910

Data from Ström O, Borgström F, Kanis JA et al. Osteoporosis: burden, health care provision and opportunities in the EU. Arch Osteoporos 2011;6:59-155.

incidence is estimated to rise from 1.66 million in 1990 to 6.26 million in 2050.⁵¹ On the basis of current trends, assuming a constant age-specific rate of fracture, hip fractures would be expected to increase in the United Kingdom from 46,000 in 1985 to 117,000 in 2016. Likewise, in the United States, as the population older than 65 increases from 32 million in 1990 to 69 million in 2050, the number of hip fractures is expected to triple. In the United States in 2005, the total number of estimated incident fractures was higher than 2 million, with 72% of the cost being accounted for by hip fractures alone. By 2025, annual fractures and cost were predicted to rise by almost 50%, with the most rapid growth seen in the 65- to 74-year-old group (87% increase) and in Hispanic and other nonwhite subpopulations (175% increase).⁵⁰

Currently, roughly half of all hip fractures in elderly people occur in Europe and North America; however, by 2050 the increasingly elderly population in Latin America and Asia could lead to a shift in the geographic distribution of hip fractures, with only a fourth occurring in Europe and North America.⁵¹

CONCLUSION

Osteoporosis is a disease that has a huge effect on public health because of its association with fracture. The impact of osteoporotic fractures is far-reaching, not only for the individual but also for the health service, economy, and population as a whole. Osteoporotic fractures are expected to rise in subsequent generations because of an increase in life expectancy and a higher proportion of elderly individuals in most countries; however, rates have fallen in many Western countries, possibly as a result of improved public screening and treatment programs. Recently, several of the risk factors for this disease have been elucidated and models have been developed to allow more accurate assessment of fracture risk in patients so that preventive and therapeutic measures can be implemented appropriately.

Clinical features of osteoporosis

■ JONATHAN H. TOBIAS

- The clinical manifestations of fractures, which are the expression of failure of bone to resist breaking, differ between fracture locations. Almost all non-spine-related fractures occur in the context of trauma and have the acute signs and symptoms of a fracture. In contrast, most osteoporotic vertebral fractures are not the result of overt trauma, and their diagnosis is frequently delayed.
- Clinical risk factors for fractures include those related to intrinsic bone strength, including low bone mineral density, and those related to the frequency, severity, and impact of falls and other types of trauma.
- Clinical risk factors can be integrated into case-finding strategies to calculate an individual's 10-year risk for a first or subsequent fracture (with or without the results of bone densitometry), thereby facilitating informed treatment decisions.
- The clinical outcome of fractures includes increased morbidity, increased risk for subsequent fractures, and increased mortality, all of which are highest within the first few years after a fracture.

INTRODUCTION

Fractures result from failure of bone to withstand external forces applied to it and occur because of intrinsic weakness of the skeleton, excessively high extrinsic force, or a combination of the two. They are associated with increased morbidity, mortality, and risk for subsequent fractures, thereby resulting in a vicious cycle of further fractures and worsening morbidity (Fig. 198.1 and Table 198.1).

Osteoporosis may be diagnosed on the basis of the presence of either a hip or vertebral fracture or low bone mineral density (BMD) as measured by dual-energy x-ray absorptiometry (DXA). Risk factors for osteoporotic fractures consist of those related to low intrinsic bone strength (i.e., osteoporosis) and those related to the frequency, severity, and impact of falls. The multitude of clinical risk factors for osteoporosis and fractures reflects their multifactorial etiology, and this has formed the basis of clinical algorithms intended to quantify fracture probability with the aim of facilitating treatment decisions. Recognizing these features is important for case finding, diagnosis, and treatment.

Clinical findings differs between fractures. In contrast to non-spine-related fractures, vertebral and stress fractures often lack the signs and symptoms of an acute fracture. They are therefore underdiagnosed and their clinical significance is frequently underestimated. The clinical outcome of fractures consists of short- and long-term increases in morbidity, mortality, and risk for subsequent fractures, and depends on the location, number, and severity of the presenting fracture. Patients with a fracture require immediate attention to optimize long-term outcomes.

CLINICAL FEATURES OF FRACTURES

Although osteoporosis is associated with increased risk for fractures throughout the skeleton, three sites, namely, the spine, distal end of the radius, and hip, have received the greatest attention to date. Nonetheless, fractures at other sites, including the pelvis, upper and lower parts of the leg, shoulder, upper part of the arm, knee, and elbow, make important contributions to the morbidity related to osteoporotic fractures.¹

Non-spine-related fractures

A cardinal feature of non-spine-related osteoporotic fractures is that although they occur in association with a defined injury, the level of trauma needed is relatively low because of the reduced intrinsic strength of the skeleton. This has led to use of the term “minimal/low-trauma fracture” in describing fractures in which underlying osteoporosis is thought to have made a major contribution.

Typically, a low-trauma fracture occurs following an event such as a fall from standing height or less when the individual is standing or walking. Certain characteristics of falls are associated with a risk of sustaining a fracture at specific sites. For example, hip fractures are thought to be related to a sideways fall, which may be more common in older subjects, thus helping explain the relatively high prevalence of hip fractures in this age group.² Falls from a greater height such as falling off a step or downstairs or falls involving greater energy, such as when running, skiing, skating, or playing sports, do not meet this definition of low trauma. However, this distinction is by no means absolute, and it seems clear that reduced intrinsic bone strength contributes to fracture risk even in the context of higher levels of trauma.³

Vertebral fractures

Radiographically evident vertebral fractures are the most common fractures in men and women.⁴ Although vertebral fractures may be seen acutely, most are clinically silent and do not have the signs and symptoms of an acute fracture. Consequently, the majority of vertebral fractures go undetected; of radiographically evident vertebral fractures, only about a third are diagnosed clinically.^{5,6} However, identification of vertebral fractures is clinically relevant because such fractures, whether clinically apparent or silent, are associated with increased morbidity,^{7,8} increased mortality,⁹ and increased risk for subsequent vertebral and nonvertebral fractures.^{10,11}

Patients with acute osteoporotic vertebral fractures often have no clearly defined preceding injury. Instead, a trivial precipitating event such lifting a heavy load may have occurred.¹² Consequently, osteoporotic vertebral fractures may be manifested as apparently unexplained new mid or low back pain. Conversely, vertebral fractures occurring after clearly defined trauma are less likely to be osteoporotic in origin. For example, vertebral fractures occurring after a fall from standing height directly onto the back generally represent traumatic rather than osteoporotic fractures.

The pain associated with acute vertebral fractures has several clinical features that may aid in diagnosis. Back pain is often very intense, exacerbated by weight bearing, and relieved by lying flat, which leads to patients spending prolonged periods in bed. Back pain secondary to vertebral fractures has also been found to have a relatively rapid onset, with many describing a sudden onset.¹² The pain can be sufficiently severe to cause breathlessness, pallor, nausea, and vomiting and is also exacerbated by coughing or sneezing. The pain frequently radiates laterally along the dermatomal distribution and is often accompanied by spasms of the paraspinal muscles. Episodes of acute, severe pain usually subside gradually within 2 to 6 weeks but can persist longer after severe fractures.

Patients with osteoporotic vertebral fractures may have a history of previous fractures or other risk factors for osteoporosis (see later). In addition, patients with vertebral fractures may report loss of height from when they were young adults. Even though a certain degree of loss of height occurs with normal aging, loss of greater than 3 cm in men and 4 cm in women may be suggestive of underlying vertebral fractures.¹³ Accurate height measurements form an essential component of the clinical assessment of patients with vertebral fractures, both to evaluate loss of height and to provide a baseline for future measurements.

Fig. 198.1 Clinical features of osteoporosis include a clinical bone- and fall-related predisposition for osteoporosis and fractures (clinical risk factors), clinical signs of fractures, and the clinical consequences of fractures (clinical outcome). The clinical consequences of fractures in survivors include physical and functional limitations, reduced quality of life, and increased risk for subsequent fractures, thereby resulting in a vicious circle of new fractures and increasing morbidity.

BOX 198.1 CAUSES OF VERTEBRAL DEFORMITY

- Vertebral fracture due to trauma
- Vertebral fracture due to osteoporosis
 - Generalized
 - Idiopathic juvenile osteoporosis
 - Osteoporosis of pregnancy
 - Localized
 - Pathologic fracture due to malignancy
 - Multiple myeloma
 - Skeletal metastases
 - Pathologic fracture due to metabolic bone disease
 - Osteomalacia
 - Primary hyperparathyroidism
 - Pathologic fracture due to osteomyelitis
- Paget disease
- Spondylosis
- Scheuermann disease
- Artifactual (scoliosis)

On clinical examination, variable degrees of kyphosis of the thoracic spine can be found in individuals with a thoracic vertebral fracture (Fig. 198.2), and flattened (reduced) lumbar lordosis is evident in those with a lumbar vertebral fracture. Loss of spinal height may be evident as a reduced distance between the bottom of the rib cage and the iliac crest, which can be quantified as finger breadths.¹⁴ Preferential loss of trunk height may also be evident by comparing standing height with arm span (measurements of which are generally equivalent). Tenderness may be elicited over the affected vertebrae and paraspinal muscles, although it is sometimes diffuse and not localized to the fractured vertebra. Mobility of the spine is restricted and movements are painful. Very restricted movements raise the possibility of a pathologic fracture related to infection or malignancy.

When an acute vertebral fracture is suspected, radiography is required to confirm its presence. Although physicians may be unwilling to refer patients with back pain for radiologic investigation, new onset of unexplained back pain in older patients should always be investigated. The investigation of choice depends on local resources but most commonly consists of a spinal radiograph. It is essential to obtain both lateral and anteroposterior views and to image both the lumbar and thoracic spine; even if a patient complains of back pain localized to one site, vertebral fractures may be present elsewhere, detection of which may be important in making management decisions. In the presence of scoliosis, lateral films in isolation may convey the mistaken impression of vertebral deformity.

Rarely, magnetic resonance imaging may be performed as the initial investigation or, more commonly, as a secondary study, depending on the results of the initial radiographs. It may be helpful in documenting the timing of the vertebral fracture based on the presence of marrow edema; confirmation that a specific fracture is recent may be important when considering interventions such as kyphoplasty. Magnetic resonance imaging may also be helpful in investigating other causes of vertebral fracture, such as malignancy. In terms of further investigations, DXA is helpful in confirming the presence of underlying osteoporosis (with the proviso that vertebrae affected by height loss be excluded from the analysis because they cause an artifactual elevation in BMD).

Vertebral deformities evident on imaging have a relatively wide differential diagnosis (Box 198.1). Those related to osteoporosis typically show characteristic wedge-shaped deformities or loss of height (see Fig. 198-2). If these findings are present and the patient has other characteristics in keeping with osteoporosis, including low BMD, it may be reasonable to accept this diagnosis. However, in certain circumstances it may be prudent to arrange further investigations to exclude other possible diagnoses; arguably, the most important of these are osteomalacia and multiple myeloma.

Conversely, minor vertebral deformities are common, particularly at the thoracolumbar junction, and can be mistaken for osteoporotic vertebral fractures, especially in the presence of other disorders such as spondylosis and particularly Scheuermann disease.¹⁵ Further evaluation of minor

vertebral deformities (e.g., by arranging for a DXA scan) may be advisable to exclude underlying osteoporosis and to reassure the patient and clinician that treatment with a bone-protective agent is not required.

From the preceding it is clear that careful evaluation of radiographs is essential to ensure that vertebral deformities are detected and that those likely to be related to osteoporotic vertebral fractures are identified correctly and reported. However, radiographic vertebral fractures are often overlooked in daily clinical practice. For example, a survey of 934 hospitalized older women with an available chest radiograph was used to evaluate the frequency with which vertebral fractures were identified and treated by clinicians.¹⁶ Moderate to severe vertebral fractures were identified in 132 (14.1%) of the study subjects, 50% of whom had a fracture recorded in the radiology report but only 17% of whom had a fracture noted in the medical record or discharge summary.

The most widespread method of evaluating spinal radiographs for the presence of vertebral deformities is the Genant semiquantitative method.¹⁵ Advantages of this method include the fact that it is relatively simple to perform and little training is required. In addition to being used in clinical research, this approach has also been recommended for use in routine clinical reporting.¹⁷ However, one limitation of this method is that patients with mild deformities (i.e., 20% to 25% loss of height) may be incorrectly labeled as having clinically significant vertebral fractures but instead may have a normal variant (i.e., “short vertebral height”).¹⁸ To overcome this shortcoming, an alternative method has been developed, the algorithm-based qualitative assessment, which uses a more specific definition based on identification of vertebral endplate fractures.¹⁹ However, the latter method requires specific training, is relatively time-consuming, and to date has not been routinely adopted into clinical practice.

Detection of vertebral fractures in patients with osteoporosis but without back pain represents a further challenge. Several attempts have been made to develop algorithms for identifying patients at highest risk for prevalent vertebral fracture, in whom spinal radiographs are most likely to be beneficial; such algorithms are based on the presence of risk factors, including age, gender, history of fracture, and loss of height.^{20,21} Some evidence suggests that implementation of such a strategy has a positive impact in targeting drug therapy in patients with vertebral fractures.²²

Vertebral fracture assessment (VFA), in which vertebral fractures are identified by inspection of lateral DXA scans, represents a further way of detecting vertebral fractures in asymptomatic individuals. The International Society for Clinical Densitometry recommends performing VFA in a number of different clinical scenarios associated with increased risk for vertebral fracture.²³ The optimal method for detecting vertebral fractures with this approach remains to be established; although current guidance proposes the application of semiquantitative methods as developed for analyzing spinal radiographs,²³ this may be overly sensitive.²⁴

Stress fractures

Stress fractures, which can also be difficult to diagnose, are a particular manifestation of fractures related to fatigue damage in bone whereby propagation of microcracks outstrips repair. *Fatigue fractures* occur in normal healthy bone repeatedly subjected to high-level stress. Such fractures are seen most commonly in track and distance runners, athletes who take part in field sports, gymnasts, dancers, and military recruits.²⁵ The most commonly affected sites include the tibia, metatarsals, and femur.²⁵ *Insufficiency fractures* occur in bone subjected to normal strain that is intrinsically weak because of osteoporosis or other metabolic bone diseases. In addition to the sites just described, insufficiency fractures commonly affect the sacrum as well. Stress fractures are often difficult to diagnose clinically and are frequently not readily recognizable on plain radiographs. Other imaging techniques, such as nuclear bone scintigraphy, computed tomography, or magnetic resonance imaging, may be needed to identify stress fractures.

CONSEQUENCES AND OUTCOME OF FRACTURES

The clinical consequences of fractures are related to the short- and long-term outcomes and differ according to fracture location (see Table 198.1) and patient characteristics. Clinical consequences include morbidity (which results in medical, hospital, and institutional care), mortality, and risk for subsequent fractures. This refracture risk is driven by a threefold to fivefold increase in risk in the years immediately after a first fracture, followed by gradual waning later (Fig. 198.3).^{10,11,26-28} The clinical consequences of hip and vertebral fractures, which are associated with substantially greater morbidity and mortality than fractures at other sites, are discussed in more detail in the following sections.

Hip fractures

Hip fractures are the most serious consequence of osteoporosis in terms of disability, mortality, and need for hospital and institutional care.²⁹ The number of hospital bed days for patients with hip fractures is higher than that for patients with stroke, diabetes, or myocardial infarction.³⁰ The combined cost of hospitalization and medical care during the 12 months after a hip fracture is approximately three times higher than that for patients without hip fractures.³¹ Patients with a hip fracture are particularly prone to complications. General (cardiovascular, pulmonary, and cerebral events and infection) and local complications (wound and problems with the implant such as dislocation, fixation failure, and infection) affect more than 30% of patients within 4 months of the hip fracture.³²

Mortality after hip fracture

In-hospital mortality ranges between 1% and 9%^{33,34} but can be as high as 55% in patients with end-stage dementia or pneumonia.³⁵ Twenty percent to 25% of patients die within the first year after a hip fracture.³⁰ After adjustment for other predictors of hip fracture, women with a hip fracture are still more than two times more likely to die than women without a fracture.¹⁰

Morbidity after hip fracture

Hip fracture has a substantial impact on morbidity and leads to reduced function and loss of independence. One study reported that after 3 months, physical performance had decreased by 51%, vitality by 24%, and social function by 26% in comparison to prefracture levels.³⁶ After 6 months, only 24% of patients had returned to their prefracture walking competence and just 43% had returned to their prefracture basic activities of daily living.³⁷ Little further improvement occurred after 1 year.^{32,38}

Of women who could dress independently before fracture, only 60% were able to do so after a hip fracture, and only two thirds were able to resume independent transfers (from bed to chair or standing from a chair).³⁹ The proportion of women who could walk across a room independently dropped from 75% before the hip fracture to 15% 6 months after the fracture. Similarly, the proportion of women able to walk one-half mile decreased from 41% before fracture to 6% 6 months after fracture, and the proportion of women able to climb stairs fell from 63% to 8%.³⁹ Only 38% of women reporting independence in several activities of daily living and basic mobility measures (including transfer from bed to chair and toilet, putting on socks and shoes, and indoor walking) recovered independence in all functions after a hip fracture.⁴⁰ Further limitations were found in cooking, performance of housework, use of transportation, grocery shopping, carrying items, taking medication, visiting friends, managing finances, and engaging in community activities.⁴¹

Indirect evidence for morbidity comes from a prospective case-control study of survivors of hip fracture.³¹ Medical and nonmedical needs were significantly higher in fracture patients than in age- and sex-matched controls. These needs were reflected in an increased number of physician contacts, increased use of physiotherapy, more days of new hospitalization and home care, and a longer stay in nursing homes.³¹

The outcome of hip fracture depends largely on preexisting comorbidity and level of function. Mortality is higher in patients living in an institution than in other patients.³⁸ In a study that adjusted for known risk factors, mortality at 6 months after hip fracture was significantly associated with prefracture mobility, health status, and the use of paid help at home.³⁴ Longer hospital stay is associated with older age, male sex, and poorer general health.³³ Patients living in an institution have a higher risk for pressure sores, surgical complications, and pulmonary and urinary infections than do patients living independently before the fracture.³⁸

Vertebral fractures

Although the back pain caused by acute vertebral fractures is generally self-limited, there is a high risk for additional vertebral fractures; such risk is increased even further in those with multiple fractures and can ultimately result in rapidly progressive disease. Patients with a prevalent (pre-existing) vertebral fracture have an approximately four times greater risk for further vertebral fractures than do patients without a prevalent fracture,²⁷ as well as twice the risk for hip and other nonvertebral fractures.¹⁰ The risk for additional vertebral fractures is extremely high in patients with multiple past vertebral fractures. For example, the risk for an additional vertebral fracture is 12 times higher in women with two or more vertebral fractures at baseline than in those without an existing vertebral fracture.⁴² After experiencing an initial vertebral fracture, 20% of postmenopausal women with osteoporosis sustain an additional vertebral fracture within 1 year.²⁷

Fig. 198.3 Risk of a second hip fracture according to time following initial hip fracture. (a) Clustering of repeated clinical fractures after menopause. (b) Hip fracture patients at risk of second hip fracture. AR, absolute risk. (a, From van Geel TA, van Helden S, Geusens PP, Winkens B, Dinant GJ. Clinical subsequent fractures cluster in time after first fractures. *Ann Rheum Dis* 2009;68:99-102; b, From Ryg J, Rejnmark L, Overgaard S, Brixen K, Vestergaard P. Hip fracture patients at risk of second hip fracture: a nationwide population-based cohort study of 169,145 cases during 1977-2001. *J Bone Miner Res* 2009;24:1299-307.)

Mortality after vertebral fracture

Mortality is higher in people after vertebral fractures than in those without vertebral fractures. The age-adjusted relative risk of dying after a vertebral fracture is as high as 8.6,⁴³ and this increase persists for at least 5 years.⁴⁴ The rate of death in patients with vertebral fractures is highest in those with multiple vertebral fractures⁴⁵ and in those who required hospitalization because of vertebral fractures.²⁶

Morbidity after vertebral fracture

Although only a third of vertebral fractures result in an acute pain episode, even vertebral fractures without acute symptoms contribute to attendant chronic morbidity.⁴⁶

Back pain

Patients with vertebral fractures are at increased risk for back pain, particularly in the lateral waist area.⁴⁷ In contrast to patients with chronic low back pain without fractures, chronic back pain after a vertebral fracture is more effectively relieved by lying down, aggravated by doing housework, and restricted to physical activity.⁴⁸ No specific circadian rhythm of pain is found. The chronic phase of back pain after an acute pain episode can last for many years, although its intensity may, but not always, decrease over time.^{48,49} In one study, half of patients with symptomatic clinically diagnosed vertebral fractures reported slight to moderate chronic pain after 4 years; the other half reported severe to intolerable pain.⁴⁸ In clinical cases, chronicity of the back pain is related to the number and severity of vertebral fractures.^{48,50,51} In other studies, pain was related to the degree of kyphosis⁵² and loss of height.⁵³ In a large cross-sectional study involving around 13,000

men and women, a positive relationship was observed between the number of vertebral deformities and back pain, irrespective of the type of deformity (i.e., wedge, biconcave, or crush fracture).¹³ However, in the latter study the strength of the relationship was relatively weak (odds ratios below 2), possibly because of the frequency of back pain in the general population.

Loss of height and kyphosis

Vertebral fractures are associated with kyphosis, which results in the typical clinical feature of a "dowager's hump" (see Fig. 198.2) and loss of height.^{13,21} During a follow-up period of 8 years, standing height decreased by approximately 1 cm with each new wedge or crush vertebral fracture but not with endplate fractures.⁵⁴ Significant loss of height has also been described in women with postmenopausal osteoporosis in control groups of clinical trials and was nearly 2.5-times greater (4.6 mm/yr) in women with new vertebral fractures than in those without vertebral fractures (1.8 mm/yr).⁵⁵

Kyphosis and loss of height also reduce the distance between the iliac crest and ribs,^{14,48} thereby resulting in problems with digestion and a protruding abdomen that makes fitting clothes difficult and detracts from appearance.⁵⁶ Loss of spinal mobility because of a vertebral fracture has been associated with difficulty dressing, standing, lying down, moving in bed, doing housework, walking, climbing stairs, washing, bathing, using the toilet, and getting to the floor.^{48,51,56} Lung function progressively decreases with increasing number of vertebral fractures and degree of kyphosis, perhaps as a result of increased abdominal pressure.⁵⁷

Physical function and quality of life

Pain, loss of height, and kyphosis secondary to vertebral fractures cause a spiraling decline in physical function, mobility, and muscle strength.^{51,52}

which affects measures of general health status and activities of daily living.^{12,48,58,59} Postural stability, which is related to the risk of falls and appendicular fractures, may also be affected.⁶⁰ Physical performance measures such as functional reach, mobility skills, 6-minute walk, and muscle strength are all significantly decreased.⁵⁹ This results in increased dependency and need for help in self-care, which is associated with moderate and severe vertebral fractures.^{12,58}

In general, the same physical and functional outcomes as in clinical cases are reported in population and case-control radiographic surveys. For example, in the Study of Osteoporotic Fractures, the odds of impaired function (difficulty in more than two activities of daily living) was 2.3 times higher in elderly women with a history of a clinically diagnosed vertebral fracture.⁶¹ New vertebral fractures, even those not recognized clinically, are associated with substantial functional limitation because of back pain in older women.⁷

A multidimensional and validated osteoporosis-targeted quality-of-life questionnaire (QUALEFFO) has been used in a population study to assess the impact of vertebral fractures.⁶² Patients with a vertebral fracture had a higher QUALEFFO score than did patients with low BMD without a vertebral fracture. The total score and its subdomains (pain, physical function, general health, and physical mobility) correlated with the number of vertebral fractures.⁶² Lumbar vertebral fractures led to greater impairment of physical function than did thoracic vertebral fractures and were associated with lower physical function, lower general health, and a lower total QUALEFFO score.⁶²

RISK FACTORS FOR OSTEOPOROSIS AND FRACTURES

In addition to the sequelae related to fractures, the clinical features of patients with osteoporosis include clinical risk factors for osteoporotic fractures, such as risk factors related to low intrinsic bone strength and risk factors for falls. These risk factors can be integrated to provide an overall estimate of fracture risk, which can be helpful in making decisions about further investigation and treatment. Osteoporosis may also occur in the context of other diseases in which osteoporosis is a secondary phenomenon and in patients found to have low BMD after DXA scanning in the absence of a recognized cause.

Clinical risk factors

Although DXA-based measurements of BMD are widely used to evaluate osteoporosis and fracture risk, many clinical risk factors for osteoporotic fracture are recognized, some of which act via BMD whereas others are thought to act independently. This has led to use of the term *bone quality* as an umbrella term for the many characteristics of bone that contribute to bone's resistance to fracture, including its structural and material components and bone turnover, some of which are clinically measurable (e.g., BMD, cortical bone size, vertebral deformities, bone turnover markers) but many of which are not (e.g., material properties).⁶³

A proposed list of major clinical risk factors for osteoporotic fractures is presented in Box 198.2.⁶⁴ Age and female sex are the strongest risk factors, consistent with the well-established descriptive epidemiology of osteoporotic fractures.⁶⁵ Other risk factors used clinically have generally been confirmed in meta-analyses of large cohorts. Previous fracture and glucocorticoid therapy were associated with approximately a doubling of risk for hip fracture as assessed in approximately 60,000 individuals¹¹ and 42,000 individuals,⁶⁶ respectively. Smoking and excessive alcohol use were associated with approximately a 50% and 100% excess risk for hip fracture, respectively, in 59,000 individuals.^{67,68} Parental hip fracture was associated with a 50%

excess risk for hip fracture in approximately 35,000 individuals.⁶⁹ Low body mass index (BMI) was associated with an increased risk for hip fracture in a meta-analysis of approximately 60,000 individuals.⁷⁰ However, the relationship between BMI and fracture risk may be complex, with recent evidence suggesting that high BMI may increase the risk for fractures at other sites such as the ankle.⁷¹ A history of falls has also been reported to be associated with an increased risk for hip fracture, although estimates vary according to study and method of adjustment.⁶⁴

Causes of secondary osteoporosis

Clinical risk factors for osteoporosis also include other disorders or treatments that are thought to cause bone loss and lead to increased risk for osteoporotic fracture. With the exception of glucocorticoid therapy, the level of evidence relating these other factors to risk for osteoporotic fracture is relatively weak. This is partly because of the relatively small number of patients involved, which prevents similar large-scale meta-analyses as those examining the relationship with glucocorticoid use. Nonetheless, although smaller numbers of individuals are affected, when causes of secondary osteoporosis are present, their impact on fracture risk may be as strong or stronger than the other clinical risk factors described earlier.

Sex hormone deficiency due to menopause is an important contributing factor in the great majority of women who develop osteoporosis. In contrast, andropause, depending on its definition, is found only in a subgroup of men with osteoporosis.⁷² Hypogonadism resulting from the treatment of breast and prostate cancer is recognized as an emerging clinical problem.⁷³ Cancer treatment-induced bone loss as a result of adjuvant endocrine therapy with an aromatase inhibitor or androgen deprivation can be considered a risk factor for the development of low BMD, osteoporosis, and bone fracture, which can be mitigated by appropriate bisphosphonate therapy.⁷³

A more complete list of causes of secondary osteoporosis, including rarer causes, is presented in Box 198.3.⁶⁴ In addition, a number of drugs have been suggested to impair bone metabolism, which may represent further risk factors for osteoporotic fractures; such drugs include anticonvulsants, selective serotonin reuptake inhibitors, thiazolidinediones, proton pump inhibitors, and antiretroviral drugs.

Fracture risk calculators

In evaluating an individual's fracture risk, as well as identifying specific risk factors and causes, it is useful to integrate these measures to provide an estimate of absolute fracture risk. The latter is helpful in making decisions

BOX 198.2 MAJOR CLINICAL RISK FACTORS FOR OSTEOPOROTIC FRACTURE

Age
Gender
Previous fragility fracture
Glucocorticoid therapy
History of falls
Family history of hip fracture
Other causes of secondary osteoporosis
Low body mass index
Smoking
High alcohol intake

BOX 198.3 CAUSES OF SECONDARY OSTEOPOROSIS

Endocrine

- Hypogonadism in either sex, including untreated premature menopause and treatment with aromatase inhibitors or androgen deprivation therapy
- Hyperthyroidism
- Hyperprolactinemia
- Cushing disease
- Diabetes

Gastrointestinal

- Celiac disease
- Inflammatory bowel disease
- Chronic liver disease
- Chronic pancreatitis
- Other causes of malabsorption

Rheumatologic

- Rheumatoid arthritis
- Other inflammatory arthropathies

Hematologic

- Multiple myeloma
- Hemoglobinopathies
- Systemic mastocytosis
- Chronic heparin treatment

Respiratory

- Cystic fibrosis
- Chronic obstructive pulmonary disease

Metabolic

- Homocystinuria
- Chronic renal disease
- Immobility

about starting treatment because it can be used to define risk thresholds above which a given therapy is likely to prove cost-effective. In addition, assessment of fracture risk based on clinical risk factors may be helpful in identifying individuals whose fracture risk is close to an intervention threshold, in whom use of DXA to provide more detailed assessment of fracture risk may be warranted.

The fracture risk tools that have been developed permit the clinician to enter information about a series of predefined risk factors on a simple Web-based platform, from which absolute fracture risk is generated. Precisely how a given risk factor is entered will depend on how the variable was handled in previous analyses underpinning the calculator; because risk factors are often reduced to binary exposures, they can often be entered only as yes/no rather than a continuous variable. It also needs to be recognized that although interactions may exist between certain risk factors, they have not been modeled in previous data sets, and thus risk calculators are unable to reflect these interactions.

Risk calculators provide an absolute estimate of fracture risk for a given individual over a fixed period. Risk for fracture is calculated for either hip fractures or major osteoporotic fractures combining the hip, spine, humerus, and distal end of the radius. The time window over which fracture risk is estimated has been subject to much debate, but calculators such as FRAX (see below) use a 10-year time window. A further uncertainty is whether the output should be rendered as fracture risk or as probability; the latter adjusts the output for survival, which has a major impact on results in older subjects, in whom 10-year fracture probability starts to fall with increasing age despite the fact that their absolute risk for fracture increases. Consequently, caution should be exercised in using assessments of 10-year fracture probability in patients older than 80 years because short-term fracture risk is likely to be underestimated.

Several fracture risk calculation tools have been developed, and they differ in a number of ways, including the strength of evidence on which they are based, how robustly their performance has been replicated in an independent data set, their ease of use, and availability. FRAX,⁷⁴ which is discussed further in the following sections, was developed at the University of Sheffield, United Kingdom, on behalf of the World Health Organization and is the leading tool internationally because it has been calibrated separately for many different countries. However, other valid tools have also been developed. For example, the QFracture risk assessment tool was based on data from approximately 2 million patients collected in the QResearch database, which is a large primary care database for England and Wales.⁷⁵ QFracture is available in the United Kingdom as a Web-based assessment tool⁷⁶ and has been reproduced successfully in an external validation study.⁷⁷ One disadvantage in comparison to FRAX is that there is no opportunity in QFracture to integrate clinical risk factors with BMD results. However, an advantage over FRAX is that a history of falls can be input as a risk factor for fracture. Unlike FRAX, which produces a 10-year probability of fracture, the output from QFracture is 10-year risk for fracture not adjusted for survival. Moreover, the output from QFracture can be adjusted to provide shorter fracture risk periods.

FRAX

The FRAX tool is based on meta-analyses of the large-scale population-based studies described earlier and includes age, sex, BMI, a history of fracture, parental hip fracture, current smoking, excessive alcohol intake, rheumatoid arthritis, glucocorticoid use, and other forms of secondary osteoporosis (Box 198.4).⁷⁴ Several studies have validated this tool in independent populations. In a study based on the Canadian FRAX tool, reasonably good agreement was observed between predicted and observed 10-year risk for hip and major osteoporotic fracture.⁷⁸ Conversely, a second independent study based on this tool found that FRAX noticeably underestimated 10-year fracture risk in higher-risk men.⁷⁹ In a further study aimed at calibrating the U.K. FRAX tool in a New Zealand population, risk for major osteoporotic fractures appeared to be overestimated, particularly when combined with BMD.⁸⁰

Application of FRAX

The 10-year fracture risk generated by FRAX can be used to decide whether to commence therapy for osteoporosis according to whether the result is above or below a predefined intervention threshold (see Chapter 197). FRAX can be calculated from clinical risk factors alone, and if the result falls within an intermediate zone, it may be an indication to arrange a DXA scan and then recalculate FRAX with BMD. In the version available in the United Kingdom, this intermediate zone has been defined by the National Osteoporosis Guideline Group in relation to their proposed age-varying intervention threshold (Fig 198.4), and links directly with the FRAX website.⁸¹ Other groups such as the National Osteoporosis Foundation have proposed age-independent intervention thresholds.⁸²

BOX 198.4 CLINICAL RISK FACTORS INCLUDED IN THE FRAX CASE-FINDING ALGORITHM

- Age (50 to 90 years)
- Sex
- Weight (in kg) and height (in cm). Body mass index is automatically computed from height and weight
- Previous fragility fracture (yes/no)
- Parental history of hip fracture (yes/no)
- Current tobacco smoking (yes/no)
- Long-term use of oral glucocorticoids ever (yes/no)
- Rheumatoid arthritis (yes/no)
- Daily alcohol consumption of 3 or more units daily (yes/no)
- Other causes of secondary osteoporosis (yes/no)
- Untreated hypogonadism in men and women (e.g., bilateral oophorectomy or orchiectomy, anorexia nervosa, chemotherapy for breast cancer, hypopituitarism)
- Inflammatory bowel disease (e.g., Crohn disease and ulcerative colitis)
- Prolonged immobility (e.g., spinal cord injury, Parkinson disease, stroke, muscular dystrophy, ankylosing spondylitis)
- Organ transplantation
- Type 1 diabetes
- Thyroid disorders (e.g., untreated or overtreated hypothyroidism)

From World Health Organization. WHO risk fracture assessment tool. Available at www.shef.ac.uk/FRAX.

BOX 198.5 GROUPS IN WHOM FRACTURE RISK SHOULD BE ASSESSED

- Women 65 years and older and all men 75 years and older
 Women younger than 65 years and men younger than 75 years in the presence of risk factors, for example:
- Previous fragility fracture
 - Current use or frequent recent use of oral or systemic glucocorticoids
 - History of falls
 - Family history of hip fracture
 - Other causes of secondary osteoporosis
 - Low body mass index (<18.5 kg/m²)
 - Smoking
 - Alcohol intake of more than 14 units per week for women and more than 21 units per week for men.

From Osteoporosis: fragility fracture risk. National Clinical Guideline Centre, 2012.

The National Clinical Guideline Centre has recently published guidelines for the use of fracture calculators such as FRAX.⁶⁴ Fracture risk assessment with such tools is recommended for all women 65 years and older and all men 75 years and older and in younger patients with risk factors (Box 198.5). It is suggested that fracture risk not be routinely assessed in people younger than 50 years unless they have major risk factors (e.g., current or frequent use of glucocorticoids, untreated premature menopause, or previous fragility fracture) because they are unlikely to be found to be at high risk. It is also recommended that fracture risk be recalculated after a minimum of 2 years if the original calculated risk was in the region of the intervention threshold for a proposed treatment or when a change has occurred in the person's risk factors. The FRAX algorithm was developed for use within a specific age range (i.e., between 40 and 90 years of age). In patients younger than 40 years, it is suggested that BMD be measured in those with a major risk factor, such as a history of multiple fragility fractures or current or recent use of high-dose steroids.⁶⁴ Patients older than 90 should be considered to be at high risk.⁶⁴

Use of FRAX is limited by the variables that are available for entry into the algorithm, which in turn reflects the available evidence base. In many clinical scenarios the characteristics of a given patient are not reflected accurately by the FRAX output, thus requiring the use of clinical judgment on a case-by-case basis. Interpretation and use of FRAX in clinical practice have been reviewed in detail.⁸³ Some of the issues that need to be considered are discussed below (Box 198.6).

Many of the FRAX risk factors, such as alcohol intake, smoking, and glucocorticoid therapy, are likely to exert dose-dependent effects on fracture risk, but they can be entered only as present or absent in the algorithm. A

Fig. 198.4 (a) After assessment of risk for fracture by using the clinical risk factors of the FRAX in the absence of bone mineral density (BMD) values, the patient may be classified as being at low, intermediate, or high risk. (b) After recalculation of fracture probability with the additional input of femoral neck BMD, the individual's risk may lie above or below the intervention thresholds for major osteoporotic fracture, hip fracture, or both. (Data from World Health Organization. WHO risk fracture assessment tool. Available at www.shef.ac.uk/FRAX.)

BOX 198.6 PRACTICAL ISSUES IN THE USE OF FRAX

Ten-year fracture risk with mortality adjustment leads to underestimation of short-term fracture risk in older patients
 No account of the dose dependency of risk factors such as alcohol, smoking, and steroid therapy
 No account of isolated reductions in spinal bone mineral density
 Uncertain performance in patients already being treated for osteoporosis
 Results need to be treated with caution in those with secondary osteoporosis
 Exclusion of fall-related risk factors
 Does not account for multiple fractures or vertebral fractures

TABLE 198.2

Percent adjustment in the 10-year probability of a hip fracture or a major osteoporotic fracture by age according to the dose of glucocorticoid

Dose	Prednisone equivalent (mg/day)	Age (yr)						
		40	50	60	70	80	90	All ages
Hip fracture								
Low	<2.5	-40	-40	-40	-40	-30	-30	-35
Medium*	2.5-7.5							
High	≥7.5	+25	+25	+25	+20	+10	+10	+20
Major osteoporotic fracture								
Low	<2.5	-20	-20	-15	-20	-20	-20	-20
Medium*	2.5-7.5							
High	≥7.5	+20	+20	+15	+15	+10	+10	+15

*No adjustment.

From Kanis JA, Johansson H, Oden A, McCluskey EV. Guidance for the adjustment of FRAX according to the dose of glucocorticoids. *Osteoporos Int* 2011;22:809-16.

refinement of FRAX has recently been published: when the entering the prednisolone dose, the result can be adjusted according to whether the dose is higher or lower than 2.5 or 7.5 mg (Table 198.2).⁸⁴ How to adjust for doses beyond 7.5 mg, which are used frequently to treat inflammatory rheumatologic disorders, remains uncertain. Moreover, although long-term use of oral glucocorticoids at any time is used as a FRAX risk factor, substantial and rapid recovery of BMD occurs after the use of glucocorticoids is discontinued,⁸⁵ thus suggesting that current steroid use represents a stronger risk factor for fracture than does previous use, but there are no means of differentiating between the two in the algorithm.

OFFSET OF FRAX RESULTS

Figure 198-5 Offset of FRAX results according to whether lumbar spine BMD is above or below that of the hip. The FRAX estimate for a major fracture should be increased or decreased by a 10th for each rounded T-score difference between the lumbar spine and femoral neck. (From Leslie WD, Lix LM, Johansson H, et al. Spine-hip discordance and fracture risk assessment: a physician-friendly FRAX enhancement. *Osteoporos Int* 2011;22:839-47.)

When using FRAX, only hip BMD is entered, and therefore a further question is how to deal with a patient whose spine BMD is considerably lower than that in the hip. Based on a study comparing observed and predicted fracture risk according to the discrepancy between hip and spine BMD, it is recommended that the FRAX estimate for a major fracture be altered by a 10th for each rounded T-score difference between the lumbar spine and femoral neck (Fig. 198.5).⁸⁶

Another question is how well FRAX performs in patients already receiving treatment, because it may be useful to repeat the fracture risk assessment sometime after therapy has commenced. Treatment effects were evaluated in 3047 women with high adherence to at least 5 years of bisphosphonate use. On comparing observed fractures with the risk predicted by FRAX,

good agreement was observed for major osteoporotic fractures, whereas incident hip fractures in those in the highest-risk tertile were significantly overestimated (observed-predicted ratio, 0.61).⁸⁷

A further issue on using FRAX is how patients with osteoporosis secondary to other causes are dealt with in the algorithm. In patients with "other causes of secondary osteoporosis" as listed in Box 198.4, the estimated fracture probability is increased if no BMD score is available. In many instances the evidence base used to weight fracture risk in persons with secondary osteoporosis is relatively weak, and these weightings are likely to change in the future as more evidence becomes available. Fracture risk in those with secondary osteoporosis is generally assumed to be mediated by reduced BMD, except in the case of patients with rheumatoid arthritis or those who have used oral glucocorticoids, in whom fracture risk is assumed to be increased independently of BMD. Consequently, when using FRAX in patients with low BMD scores, those receiving glucocorticoids for rheumatoid arthritis are frequently shown to have a relatively high risk for fracture in comparison to patients with other causes of secondary osteoporosis.

One limitation of FRAX is that unlike QFracture, fall-related risks are excluded despite the fact that a history of falls is a major risk factor for future fracture. For example, in an integrated bone- and fall-related risk evaluation tool for estimation of the 5- and 10-year absolute risk for fracture in patients taking glucocorticoids, a history of falls had a greater impact on fracture risk than did any other evaluated risk, and its contribution to fracture risk was similar to—and independent of—the use of high-dose glucocorticoids.⁸⁸

A further issue with FRAX is that fracture risk may be underestimated in patients with multiple fractures or vertebral fractures because a history of a previous fragility fracture is entered as being present or absent, irrespective of the number of previous fractures or site. For example, although a history of a previous fracture is associated with an approximately twofold increase in subsequent fracture risk,¹¹ fracture risk is increased approximately fourfold in those with a vertebral fracture.^{27,42}

Pathophysiology of osteoporosis

■ ELIZABETH A. STREETEN ■ SARADA JAIMUNGAL ■ MARC C. HOCHBERG

- Osteoporosis is a disease characterized by reduced bone strength and increased susceptibility to fractures. The reduction in bone strength is a function of reduced bone mass and abnormal bone quality. Determinants of bone quality include bone microarchitecture, geometry, turnover, mineralization, and osteocyte viability.
- Peak bone mass is highly heritable, with genes controlling 60% to 85% of the variance at different skeletal sites. Small contributions from each of at least 60 genes contribute to this heritability. Genes identified as having an impact on bone mass include those involved in bone formation through the Wnt pathway (e.g., low-density lipoprotein receptor–like protein 5), bone resorption through the RANK-RANKL-OPG pathway, steroid hormone receptors (e.g., estrogen, vitamin D), bone proteins (e.g., type 1 collagen, bone morphogenetic protein), growth factors (e.g., insulin-like growth factor-1, transforming growth factor- β), and cytokines (e.g., interleukin-6).
- Vitamin D deficiency (defined variably as serum 25-hydroxyvitamin D levels <20 ng/mL [Institute of Medicine] or <30 ng/mL [Endocrine Society]) plays a strong role in osteoporosis, both as a result of increasing rates of bone loss and possibly by contributing to muscle weakness, impaired balance, and increased risk for falling.
- Bone remodeling describes the process by which old bone is continuously replaced by new. Net gain or loss of bone at a particular skeletal site is determined by the balance between bone resorbed by osteoclasts and bone formed by osteoblasts.
- Osteoclasts are activated by membrane signaling through RANK, the cognate receptor for RANKL, which is a member of the family of tumor necrosis factor ligands expressed on marrow stromal cells (including osteoclast precursors) and osteoblasts. The RANKL/RANK interaction promotes the differentiation of osteoclast precursors and increases the activity and life span of mature osteoclasts.
- Although aging and hypogonadism are universal risk factors for bone loss, many other factors play an important role, including chronic diseases, genes, medications, lifestyle, and environmental factors.

INTRODUCTION

Osteoporosis is a disease characterized by reduced bone strength and increased susceptibility to fracture. The reduction in bone strength is a function of both reduced bone mass and abnormal bone quality. Determinants of bone quality include bone microarchitecture, geometry, turnover, damage accumulation, mineralization, and osteocyte viability. Osteoporosis is generally asymptomatic until clinical sequelae (fractures) occur. Osteoporotic fractures are associated with increased mortality and morbidity, including pain, disability, and deformity. The ability to measure bone mass with increasing detail by noninvasive means and progress in understanding the genes related to bone formation and fracture have shed significant light on the pathogenesis of osteoporosis. Osteoporosis is a complex disease with multiple genetic, hormonal, and environmental influences. This chapter briefly reviews the role of these factors in the development of osteoporosis.

DETERMINANTS OF BONE MASS

Bone mass at any time in life is the integral of the amount of bone accrued during growth and consolidation (peak bone mass) and the inevitable loss of bone with aging. Both factors contribute to risk for fractures.

Peak bone mass

Bone mass peaks by the early 20s in women and mid-20s in men and is determined principally by genetic factors. Lifestyle and environmental factors are also important, as are gene-environment interactions. At skeletal maturity, men have 5% to 10% greater bone mass than women do because of sexual dimorphism in periosteal bone apposition at puberty.¹ In boys, higher androgen levels cause greater periosteal apposition; in girls, estrogen inhibits this process.²

Genetic factors

Genes influence not only peak bone mass but also bone loss with aging.³ Genome-wide association studies (GWASs) using meta-analyses of population-based databases of up to 70,000 individuals have identified more than 60 genes related to bone health, thus expanding our knowledge of bone physiology.^{4,5} Genes identified include those related to (1) the Wnt pathway, which is critical for bone formation; (2) the RANK-RANKL-OPG (receptor activator of nuclear factor κ B and its ligand, osteoprotegerin) pathway, which activates osteoclasts to resorb bone; and (3) endochondral ossification, which is important for the formation of long bones. In addition, GWASs have confirmed the contribution of genes related to vitamin D and parathyroid function. Each gene identified contributes no more than 3% of the total genetic influence on bone health. In conglomerate, identified genes explain less than 30% of the total genetic influence on bone health. Identification of genes related to bone turnover has directly led to new drugs for osteoporosis, such as denosumab, a human monoclonal antibody to RANKL.⁶ In addition, antibodies to sclerostin (SOST)⁷ and cathepsin K⁸ are currently in clinical trials for osteoporosis. Sclerostin, produced by osteocytes, inhibits the Wnt pathway; conversely, inhibition of sclerostin stimulates the Wnt pathway, thereby increasing bone formation. Cathepsin K, produced by osteoclasts, is an enzyme that dissolves bone matrix.

Identification of genes causing monogenetic disorders of osteoporosis has given great insight into the pathogenesis of osteoporosis. For example, in 2001 a rare syndrome of childhood osteoporosis and congenital blindness, osteoporosis pseudoglioma syndrome, was found to be due to inactivating mutations in *LRP5* (protein product low-density lipoprotein receptor–like protein 5), a key regulator of the Wnt pathway.⁹ Activating mutations in *LRP5* cause nonsyndromic high bone mass.¹⁰ In the general population, *LRP5* has been shown to be important for mechanosensation of bone and mediates the response of bone to physical activity.¹¹

The effects of genes are modulated by hormonal factors, which in themselves are genetically regulated. For example, 33% of the variance in peak bone mass can be explained by variations in endogenous growth hormone production, even after adjustment for height.¹²

There are also racial differences in peak bone mass and fracture risk, with blacks having 5% to 10% greater bone mass than whites and lower fracture risk. This is despite lower serum 25-hydroxyvitamin D (25[OH]D) levels, lower average calcium intake, and higher parathyroid hormone (PTH) levels in blacks than in whites. This discrepancy can be explained by the resistance

of the skeleton in blacks to the bone-resorbing effects of PTH, presumably an adaptive response to reduced cutaneous vitamin D production.¹³

Nutrition

Several nutrients play a key role in skeletal development, including calcium, phosphorus, and vitamin D. Greater lifetime dietary calcium intake is directly related to peak bone mass and indirectly to hip fracture rate.¹⁴ In 2011, the Institute of Medicine (IOM) set the recommended daily intake of calcium at 700 mg for children 1 to 3 years of age, 1000 mg for those 4 to 8 years of age, 1300 for those 9 to 18 years of age, 1000 mg for adults 19 to 50 years of age, 1000 mg for men 51 to 70 years of age, 1200 mg for women older than 50 years, and 1200 mg for men older than 70 years.¹⁵ The IOM report also recommended daily vitamin D intake of 600 IU for those aged 1 to 70 years and 800 IU for those older than 70 years, an increase from previous recommendations. Although sunlight exposure allows skin to produce vitamin D endogenously, use of sunblock and increasing avoidance of sun exposure are contributing to an epidemic of vitamin D inadequacy in the young and old.

Exercise

According to Wolff's law, bone adapts to the load applied to it, and the higher mechanical load experienced during exercise leads to an increase in bone density, particularly during childhood. High-impact exercise appears to confer the greatest benefit. Participation in weight-bearing sports during childhood has a positive influence on peak bone mass,¹⁶ and the positive effects persist into adulthood. Among different active sports participants, gymnasts have greater bone density than runners do, whereas swimmers and cyclists have the lowest bone density.¹⁷ School-based exercise interventions have been found to improve bone mass in children,¹⁸ particularly those that include jumping.

Gonadal function

Ovarian and testicular dysfunction can adversely affect peak bone mass. In women with amenorrhea as a result of excessive exercise, anorexia nervosa, and hyperprolactinemia, the deficit in bone mass is partially reversible if normal ovarian function is resumed, but the longer the duration of amenorrhea, the less bone mass can be regained.¹⁹ In men, hypogonadism as a result of Klinefelter syndrome and androgen receptor mutations has been associated with low bone mass.²⁰

Bone loss

Age-related bone loss is a universal phenomenon that occurs at almost all skeletal sites, in all races and cultures, and in both men and women. The rate of age-related bone loss is influenced by genetic, endocrine, and environmental factors.

Nutrition: calcium and vitamin D

Adequate calcium intake, by calcium supplementation if necessary, retards bone loss in postmenopausal women. Some, but not all studies have shown that calcium plus vitamin D supplementation reduces fracture risk; reduction of the risk for hip fractures requires a vitamin D dose of at least 800 IU daily.²¹ The serum level of 25(OH)D that defines vitamin D deficiency is controversial—20 ng/mL according to the IOM¹⁵ and 30 ng/mL according to the Endocrine Society.²² The discrepancy is primarily due to different interpretations of data related to 25(OH)D and bone health. Given the higher level of 25(OH)D considered to be normal by the Endocrine Society, it is not surprising that higher vitamin D intake is recommended (than by the IOM), up to 2000 IU daily for adults at risk for vitamin D deficiency.²² Vitamin D deficiency also contributes to muscle weakness, impaired balance, and increased risk for falls,^{23,24} thereby increasing the risk for fracture.²⁵ Low levels of 25(OH)D have been associated with numerous diseases besides osteoporosis, including cancer, diabetes, autoimmune diseases, and cardiovascular disease.²⁶ However, large prospective, controlled studies are needed to confirm that correcting vitamin D deficiency reduces the risk for these diseases.

Nutrition: other dietary factors

Patients with hip fractures are frequently malnourished, with inadequate protein intake, and protein supplementation has been found to reduce complications after hip fracture.²⁷ Dietary phosphate or magnesium deficiency may both accelerate bone loss.²⁸ Similarly, several studies have shown that vitamin C and K deficiencies may increase fracture risk.²⁹⁻³¹ By contrast, excess vitamin A may cause bone loss and increased risk for hip fractures.³² Elevated serum homocysteine levels have been associated with bone loss and fracture risk only in women.³³

Alcohol and smoking

High alcohol consumption (more than two servings in women and more than four servings in men daily) inhibits bone formation and results in an increase in hip fracture risk.³⁴ Safe daily alcohol intake for bones is one serving for women and two for men.³⁵ Smoking increases the risk for fracture,³⁶ delayed fracture healing, and postoperative complications.³⁷ Smoking exerts a toxic effect on osteoblasts, leads to earlier menopause, and reduces the production while accelerating the degradation of estrogen. In men, smoking is associated with increased levels of both testosterone and estradiol, as well as increased risk for osteoporosis and fracture.³⁸

Physical activity

Immobilization results in rapid and profound bone loss. In contrast, weight bearing and resistance exercises improve bone mass, slow bone loss,³⁹ and reduce fracture risk.⁴⁰

Chronic diseases and medications

Many chronic diseases and disorders are associated with enhanced bone loss and increased risk for osteoporosis (Table 199.1). Numerous medications (Table 199.2) are known to have detrimental effects on the skeleton, including glucocorticoids, which inhibit bone formation by promoting osteoblast and osteocyte apoptosis, reducing gastrointestinal absorption of calcium and

TABLE 199.1
Medical conditions associated with osteoporosis

System	Disease
Cardiac	Congestive heart failure
Endocrine and metabolic	Acromegaly
	Adrenal insufficiency
	Cushing syndrome

	Rheumatoid arthritis
	Scoliosis

increasing renal calcium excretion.⁴¹ Anticonvulsants decrease bone mass primarily by increasing vitamin D catabolism and increasing bone resorption; thiazolidinediones⁴² decrease bone mass by promoting maturation of bone marrow stromal cells into adipocytes rather than osteoblasts.

PATHOGENESIS OF BONE LOSS

The effects of these risk factors on increasing bone loss are mediated through changes in the bone-remodeling cycle.

Bone remodeling

Bone remodeling describes the process by which resorption of old bone is continuously replaced by the formation of new bone. The balance between resorption and formation determines whether there is net loss or gain of

bone tissue at a particular skeletal site. Bone remodeling is accomplished by osteoclasts, osteoblasts, osteocytes, and other accessory cell types, referred to as bone-remodeling units (BRUs).⁴³ The three-dimensional geometry of the newly modeled bone occurs in discrete entities called osteons or packets. The structures of cortical and cancellous bone are distinctly different (Figs. 199.1 to 199.3), but the cellular processes are essentially the same.

Osteoclast activation and resorption

The first event in the cycle is activation. During activation, mononuclear osteoclast precursors, derived from circulating monocytes or bone marrow macrophage precursors, fuse on the bone surface to form multinucleated osteoclasts. Evidence is mounting that activation is triggered by the death or disruption of nearby osteocytes, with the resultant microdamage serving as a target for bone remodeling.⁴⁴ Differentiated osteoclasts degrade the organic and inorganic components of the bone matrix. In cancellous bone and on the endosteal and periosteal surfaces of cortical bone, osteoclasts move along the bone surface. In cortical bone they tunnel through the bone and make a cylindric hole.

The formation, activation, and activity of osteoclasts are regulated by local cytokines, including RANKL, interleukin-1 (IL-1) and IL-6, colony-stimulating factors, and systemic hormones such as PTH, 1,25-dihydroxyvitamin D₃, and calcitonin.⁴⁵ Osteoclast resorption is achieved by signaling through RANKL/RANK interaction⁴⁶ (Fig. 199.4).

Reversal and formation, osteocytes

The resorption phase is followed by the reversal phase. Osteoclasts die by apoptosis and are replaced by osteoblasts, thereby initiating the formation phase.⁴⁷ On bone surfaces, osteoblasts refill the resorption pits (cancellous bone) and tunnels (cortical bone) with new units of lamellar bone, referred to as osteon or packets (see Fig. 199.2).

In the formation phase, osteoblasts are buried in matrix and become osteocytes. Osteocytes communicate with one another via a large, three-dimensional, functional lacunocanalicular network that can “sense” a change in the mechanical properties of the surrounding bone and communicate this information to osteoblasts and osteoclasts to regulate bone remodeling.^{48,49} With bone unloading, osteocytes produce more sclerostin, which suppresses bone formation.⁵⁰ Mutations in the gene for sclerostin (SOST) lead to the sclerosing bone disorder sclerosteosis/Van Buchem disease.⁵¹ Other factors involved in the crosstalk among bone cells include IL-33 (produced by osteoblasts), which inhibits osteoclast formation, and the cytokine cardiotrophin-1 (produced by osteoclasts), which stimulates osteoblast bone formation.⁵²

TABLE 199.2 Medications associated with osteoporosis	
System	Medication
Endocrine	Aromatase inhibitors (e.g., anastrozole)
	Excess thyroxine replacement
	Glucocorticoids
	Gonadotropin-releasing hormone agonists
	Ovarian-suppressing drugs (e.g., medroxyprogesterone acetate)
Gastrointestinal	Thiazolidinediones
	Proton pump inhibitors
Hematologic	Heparin
	Warfarin
Infectious disease	Antiretroviral therapy
Immunosuppressant	Cyclosporine
	Cytotoxic drugs
	Tacrolimus
Neurologic	Anticonvulsants—phenytoin, phenobarbital, carbamazepine
Psychiatric	Selective serotonin reuptake inhibitor
Renal	Loop diuretics (e.g., furosemide)

Fig. 199.1 The arrows indicate the direction of movement through space. Note that the cancellous bone-remodeling unit (BRU) is essentially half the cortical bone-remodeling unit. (From Dempster DW. *New concepts in bone remodeling*. In: Seibel MJ, Robins SP, Bilezikian JP, editors. *Dynamics of bone and cartilage metabolism*. San Diego: Academic Press; 1999, p. 261-73.)

Fig. 199.2 Intact bone packet in human cancellous bone (a) and intact haversian system in human cortical bone (b). Note the osteons that have been partially replaced by prior remodeling events. (From Dempster DW. Bone remodeling. In: Coe FL, Favus MJ, editors. *Disorders of bone and mineral metabolism*. 2nd ed. Philadelphia: Lippincott, Williams & Wilkins; 2002, p. 315-43.)

Fig. 199.3 (From Meunier P, Courpron P, Edouard C, et al. *Physiological senile involution and pathological rarefaction of bone: quantitative and comparative histological data*. *Clin Endocrinol Metab* 1973;2:239-56.)

Gender and other influences on remodeling

Women lose more bone with age than men do. By 90 years of age, women have lost 25% of their peak cortical bone mass versus 18% in men and 55% of their trabecular bone (in central sites) versus 46% in men.⁵³ In both sexes, the reduction in serum estradiol with age is an important mediator of bone loss.⁵³ In men, aging results in a gradual decrease in osteoblast function, decreased thickness of cancellous bone packets, trabecular thinning, and a linear reduction in cancellous bone volume with age (see Fig. 199.3). Trabecular connectivity is better preserved in men than in women.⁵⁴

At menopause women have an abrupt acceleration in the rate of bone loss for 5 to 10 years (see Fig. 199.3), primarily because of enhanced osteoclast activity via increased RANKL production.⁵⁵ RANKL production is further increased with aging as a result of secondary hyperparathyroidism caused by renal insufficiency, vitamin D deficiency, and a reduction in activation of vitamin D.⁵⁶ Osteoclasts ultimately remove many trabeculae. The reduced trabecular number decreases bone strength much more than trabecular thinning does.⁵⁷

Strong bidirectional links have been shown between bone and energy metabolism. Osteoblasts and adipocytes share a common progenitor cell, the mesenchymal stem cell (MSC). Although bone volume decreases with age, marrow adiposity increases.⁵⁸ Factors that control differentiation of MSCs into osteoblasts include lamin A/C (nuclear protein important for

gene expression), RUNX2 (transcription factor), and the bone morphogenetic protein, Wnt, and Notch signaling pathways.^{59,60} Age-related changes in lamin A/C and RUNX2 expression lead to bone loss. Secretion of leptin by adipocytes reduces bone production, and secretion of osteocalcin by osteoblasts improves insulin sensitivity.⁶¹ Adding further complexity, the sympathetic nervous system has an effect on bone remodeling. Patients taking β -blockers have higher bone mass and fewer fractures.⁶²

Strength of cancellous bone

At weight-bearing sites, struts of trabeculae are aligned in the direction of the primary load axis and are supported by trabeculae oriented perpendicular to the load axis (serving as cross-ties). With aging and osteoporosis, there is preferential loss of cross-ties.⁶³ According to Euler's theorem, the buckling load of a weight-bearing trabecula decreases inversely with the square power of its unsupported length. Thus loss of two cross-ties will triple the effective length of the trabecula to which it was connected, but the load that the trabecula can support will decrease by a factor of 9. Loss of cross-ties and other architectural changes that compromise bone quality have been demonstrated in patients with hip fractures.⁶⁴⁻⁶⁷

Effects on long bones

With aging, long bones increase in diameter and their cortex thins because of small imbalances in bone resorption and formation in each remodeling

Fig. 199.4 Crosstalk between bone cells. The balance between bone formation and resorption is largely regulated by the Wnt pathway (bone formation), receptor activator of nuclear factor κ B (RANK)/RANK ligand (RANKL) pathway (osteoclast activation), and sclerostin (negative regulation of bone formation). Osteoblasts express the cell surface receptors RANK and also secrete a soluble decoy receptor, osteoprotegerin (OPG), a member of the superfamily of tumor necrosis factor receptors. Wnt protein binds the coreceptors Frizzled and low-density lipoprotein receptor-like proteins 5 and 6 (LRP5/6), which leads to stabilization of β -catenin and its translocation to the nucleus to regulate target genes, thereby resulting in increased bone formation. In the absence of OPG, RANKL on the osteoblast surface is available to bind the RANK present on osteoclast precursors. Binding of RANK/RANKL leads to osteoclast maturation and resorption of bone. Sclerostin, secreted by osteocytes, inhibits Wnt from binding LRP5.

cycle. The balance is negative on the inner, endosteal surface and positive on the outer, periosteal surface. Women lose more bone from the endosteal surface than men do,⁶⁸ which results in greater loss of the cross-sectional moment of inertia with age in women and greater fracture risk. Within the

cortex, women have more age-related declines in the area occupied by circumferential lamellar bone, greater increases in haversian canal diameter, and greater decreases in osteon wall thickness than men do, all leading to greater cortical porosity and higher risk for fracture.⁶⁹

Biochemical markers in bone disease

■ KIM E. NAYLOR ■ RICHARD EASTELL

- Specific and sensitive assays are available for the measurement of biochemical markers of bone turnover.
- The International Osteoporosis Foundation recommends that serum PINP and CTX-I be used as reference analytes in clinical and research studies to allow comparison of results.
- Bone turnover markers that have shown reliable performance in studies of osteoporosis are bone alkaline phosphatase, total osteocalcin, PINP, CTX, and NTX.
- Markers can reflect posttranslational modification of collagen.
- Bone turnover markers are clinically useful for monitoring the efficacy of antiresorptive therapy in women with postmenopausal osteoporosis.

INTRODUCTION

Bone remodeling is a continuous process that contributes to the preservation of skeletal health and regulation of calcium homeostasis. It is normally a coupled process that occurs in local areas called bone multicellular units (BMUs)^{1,2} and is regulated by systemic hormones and local factors. During the bone resorption phase, bone tissue is broken down by osteoclasts, which produces a resorption cavity (Fig. 200.1). This cavity is then filled with new bone synthesized by osteoblasts during the bone formation phase. Bone remodeling and the number of BMUs are normally in steady state; however, an imbalance can occur, for example, with changes in age, hormonal status, or mobility or with disease or medications.³ In some diseases, such as postmenopausal osteoporosis, the increase in bone resorption is greater than the increase in bone formation, thereby resulting in net bone loss (see Chapter 199). In glucocorticoid-induced osteoporosis, on the other hand, bone loss is due to a reduction in osteoblast function leading to a decrease in bone formation (see Chapter 202).

Biochemical markers of bone turnover provide a noninvasive method of assessing changes in bone metabolism.⁴⁻⁷ They are divided into markers of bone formation and bone resorption (Box 200.1). In disease states in which bone turnover remains coupled and changes in the same direction, both bone formation and bone resorption markers will reflect the rate of bone turnover. Not all markers of bone turnover are specific to bone because some can be found in other tissues. Type I collagen accounts for approximately 90% of the organic matrix of bone.⁸ Several bone turnover markers are based on byproducts of type I collagen synthesis or degradation. Other bone markers include markers of enzymatic activity or bone matrix proteins that are released into the circulation during bone remodeling. Bone turnover markers reflect the whole-body net changes in the skeleton and cannot discriminate between changes in turnover in a specific skeletal envelope. New markers are emerging, including regulators of bone turnover (Box 200.2).

Bone markers are useful for assessment of metabolic bone disease; however, they are most widely used in women with postmenopausal osteoporosis. Several studies have assessed the use of bone markers to predict fracture and their role in monitoring the efficacy of treatments. This chapter reviews recent developments in the methodology and use of bone markers for the management of metabolic bone disease.

BIOCHEMICAL MARKERS OF BONE TURNOVER

Bone resorption

Bone resorption markers include products of osteoclast activity and type I collagen degradation. Bone resorption markers are predominantly based on type I collagen degradation products. Hydroxyproline was one of the first markers of bone resorption but lacked specificity for bone. More specific markers were developed with assays for the measurement of type I collagen cross-links (pyridinoline [PYD] and deoxypyridinoline [DPD]) in urine by high-performance liquid chromatography.^{9,10} Free DPD can also be measured by enzyme-linked immunosorbent assay.¹¹ More recently, the telopeptides of type I collagen have been established as bone resorption markers.^{12,13} These telopeptides are nonhelical peptide fragments of type I collagen that contain the following cross-linking regions: the N-terminal cross-linked telopeptide of type I collagen (NTX)^{13,14} and the C-terminal telopeptide of type I collagen (CTX) generated by cathepsin K.¹⁵ Assays have also been developed for the C-telopeptides generated by metalloproteinase (CTX-MMP or ICTP).¹⁶

Because reference markers for bone turnover have not been established, it is difficult to directly compare published results from clinical studies. The International Osteoporosis Foundation (IOF) has recommended CTX as the reference marker for bone resorption.^{17,18} However, because CTX is reduced by feeding, it is recommended that samples be collected after an overnight fast. Urine NTX measurements can be made on second-void morning samples collected before attendance at the clinic, which makes them more convenient for some patients.

An interesting property of type I collagen telopeptides is nonenzymatic posttranslational modification of the (1209)AHDGGR(1214) sequence of CTX, which is thought to reflect bone matrix maturation (Fig. 200.2). The native α form of the C-telopeptide of type I collagen (α -CTX) is found in newly synthesized type I collagen. The carboxyl group in position α of aspartic acid is involved in a peptide bond with the adjacent glycine residue. As maturation of the collagen occurs, it undergoes β -isomerization with spontaneous translocation of the peptide bond to the carboxyl group in position β of the aspartic acid (D) residue within the C-telopeptides of the α 1 chains.^{12,19} The resulting β -CTX isomerized sequence alters the three-dimensional conformation of type I collagen. The native (α) and isomerized (β) CTX are measured with specific immunoassays, available as both manual assays and assays by automated analyzers.

Other bone resorption markers include osteoclastic enzymes such as tartrate-resistant acid phosphatase (TRAcP) and cathepsin K. Sensitive immunoassays are available for TRAcP type 5b, which is expressed by osteoclasts^{20,21} and mainly reflects osteoclast number. Cathepsin K can be measured by immunoassay, but further evaluation of its use as a marker of bone resorption is required.²²

Bone formation

Type I collagen is synthesized in the early phase of bone formation. During this process the amino and carboxy propeptides of type I procollagen (PINP, PICP) are released into the circulation.^{23,24} The IOF selected PINP as the reference marker for bone formation because of its robust nature and dynamic response to treatment.^{17,18}

Bone alkaline phosphatase is an enzyme associated with matrix maturation and accounts for around half of the total alkaline phosphatase in the circulation.²⁵ Total alkaline phosphatase is a suitable marker for assessment of metabolic bone diseases associated with large changes in bone turnover, such as Paget disease of bone. However, the bone isoenzyme of alkaline

Fig. 200.1 Local and systemic factors initiate activation of the bone-remodeling cycle. Osteoclasts break bone down during the resorption phase, which creates a cavity. Mononuclear cells signal the initiation of bone formation by osteoblasts. New bone replaces the bone removed from the erosion cavity. A period of quiescence occurs before the next remodeling cycle begins.

BOX 200.1 BIOCHEMICAL MARKERS OF BONE TURNOVER

Bone resorption markers

Collagen degradation products

Pyridinoline (PYD), deoxypyridinoline (DPD)

Telopeptides of type I collagen:

C-terminal (α / β -CTX, ICTP, or CTX-MMP)

N-terminal (NTX)

Osteoclast enzymes

Tartrate-resistant acid phosphatase 5b (TRAcP-5b)

Bone formation markers

Collagen synthesis byproducts

Type I procollagen C-terminal and N-terminal propeptides (PICP, PINP)

Matrix proteins

Intact and total osteocalcin (OC)

Osteoblast enzymes

Total alkaline phosphatase (total ALP)

Bone alkaline phosphatase (bone ALP)

BOX 200.2 NOVEL BIOCHEMICAL MARKERS OF BONE METABOLISM

Regulators of osteoclast-osteoblast differentiation/activity

OPG/RANKL Wnt signaling molecules (Dkk-1/sFRP)

Sclerostin

Noncollagenous proteins

Bone sialoprotein

Osteopontin

Periostin

Urinary midmolecule osteocalcin

Osteoclast enzymes

Cathepsin K

Markers of bone matrix properties

Nonenzymatic glycation-mediated modifications of collagen, (e.g., pentosidine, vesperlysine, carboxymethyllysine)

Carboxylation and isomerization of osteocalcin

Type I collagen C-telopeptide isomerization (α / β -CTX ratio)

Dkk-1, Dickkopf-1; sFRP, soluble Frizzled-related protein; OPG, osteoprotegerin; RANKL, receptor activator of nuclear factor κ B ligand.

phosphatase is more specific and can detect more subtle changes in bone turnover.

Osteocalcin is a bone matrix protein produced by osteoblasts and is expressed at the mineralization phase of bone formation. Osteocalcin is incorporated into the bone matrix, and a small fraction is released into the circulation both as intact molecules and as fragments. Assays are available that measure the intact molecule and the large N-terminal midfragment.²⁶ It has been suggested that osteocalcin fragments could be released during bone resorption.²⁷

Vitamin K is required for γ -carboxylation of the three glutamic acid residues necessary for the mineral-binding ability of osteocalcin. Undercarboxylated osteocalcin is a measure of vitamin K insufficiency,²⁸ and increased levels are associated with risk for hip fracture.²⁹ It has been proposed that this form of osteocalcin has a role in energy metabolism by stimulating insulin secretion and increasing insulin sensitivity.³⁰

REGULATORS OF BONE TURNOVER

The osteoprotegerin (OPG)/receptor activator of nuclear factor κ B (RANK)/RANK ligand (RANKL) system is one of the key mediators of osteoclast differentiation and action.³¹ Imbalances in this pathway are associated with postmenopausal bone loss. Circulating OPG and RANKL have been shown to be affected by different diseases; however, conflicting data have been reported in clinical studies.³² OPG inhibits osteoclastogenesis, thereby resulting in a decrease in bone resorption. Circulating OPG was not associated with the reported change in bone markers in some studies.^{33,34} Circulating OPG levels are higher in patients with osteoporosis than in controls.³⁵ The clinical utility of OPG and RANKL as bone turnover markers remains to be fully evaluated.

Novel markers

The Wnt signaling pathway is central to the regulation of bone metabolism; it plays a pivotal role in osteoblast cell growth, differentiation, and apoptosis.³⁶ The Wnt ligands primarily signal through the seven-transmembrane receptor complex of the Frizzled family. The Frizzled-related proteins (FRPs) each interact with the low-density transmembrane lipoprotein receptor-related protein-5/6 (LRP-5/6). The Wnt signaling pathway is inhibited by proteins that prevent ligand receptor binding such as Dickkopf-1 (Dkk-1) and soluble FRPs. Alterations in the Wnt signaling pathway have been associated with conditions of abnormal bone turnover and bone loss. Elevated Dkk-1 has been associated with conditions characterized by suppressed bone formation and osteolysis (e.g., multiple myeloma, bone metastasis, and rheumatoid arthritis). Treatment with bisphosphonate anti-resorptive therapy results in a decrease in Dkk-1.³⁷

Sclerostin

Sclerostin is a protein containing 188 amino acids with two N-glycosylation sites.³⁸ It is secreted by osteocytes and inhibits the genesis of osteoblasts, thereby resulting in a decrease in bone formation. Circulating sclerostin levels are higher in postmenopausal than in premenopausal women.³⁹⁻⁴¹ Sclerostin was found to be modestly associated with bone mineral density (BMD) and bone turnover in a population-based study of postmenopausal women.⁴²

Elevated sclerostin is associated with a greater risk for hip fractures in older women, particularly those with low BMD (Fig. 200.3).⁴³

Measurement of sclerostin is not yet suitable for use in clinical practice because the assays need to be optimized and standardized since the data from different assays are discordant.⁴⁴ The circulating molecular forms have not been characterized (intact or fragments). The kinetics still needs to be determined. It is unclear what percentage of sclerostin enters the circulation from bone, whether the rate of production is related to bone mass, and what the clearance mechanism is. Even though sclerostin levels are increased in those with chronic kidney disease, the increase in sclerostin with age is not explained by the decline in the estimated glomerular filtration rate.⁴⁵

Sources of variability also need to be explored. Levels of sclerostin are reported to be higher in men than in women, as well as higher in older people. Sclerostin levels are increased for up to 48 weeks following fracture of a long bone.⁴⁶ Variability could be altered in metabolic bone diseases with a high bone turnover state such as Paget disease of bone and prostate cancer with bone metastases. Further studies are required to determine the effects of other sources of variability, such as circadian rhythm, effect of meals, day-to-day and seasonal variability, ethnicity, race, and geographic location.

Fig. 200.2 Type I collagen is formed by the association in a triple helix of two α_1 and one α_2 chains except for the two ends (N- and C-telopeptides). In bone matrix, type I collagen is subjected to different posttranslational modifications: the mature trivalent cross-links, including pyridinoline (PYD), deoxypyridinoline (DPD), and pyrrole, that make bridges between two telopeptides and the helicoidal region of another collagen molecule. These molecules result from the maturation of divalent cross-linking molecules (dihydroxylysinoxonoreucine [DHLNL] and hydroxylysinoxonoreucine [HLNL]) whose synthesis requires an enzymatic process (lysyl oxidase); the advanced glycation end products (AGEs) are formed by nonenzymatic glycation when sugar (e.g., glucose) is present in the extracellular matrix. Some AGEs, such as pentosine, are cross-linking molecules, although their precise location remains to be determined; the nonenzymatic isomerization of aspartic acid (D) occurs in the C-telopeptides of α_1 chains. CTX, C-terminal telopeptide of type I collagen.

Fig. 200.3 The median bone mineral density (BMD) (0.742 g/cm^2 ; T-score, -1.6) was chosen as a cutoff point. Lower BMD is defined as less than 0.742 g/cm^2 and higher BMD as 0.742 g/cm^2 or higher. Serum sclerostin quartiles are as follows: quartile 1, 209 pg/mL; quartile 2, 210 to 267 pg/mL; quartile 3, 268 to 353 pg/mL; and quartile 4, higher than 353 pg/mL. The hazard ratio (HR) for the risk for hip fracture (95% confidence intervals) as compared with higher BMD/quartile 1 are as follows: higher BMD/quartile 2, HR = 1.8 (0.4 to 7.3); higher BMD/quartile 3, HR = 5.0 (1.3 to 18.7); higher BMD/quartile 4, HR = 7.3 (2.0 to 26.3); lower BMD/quartile 1, HR = 8.7 (2.4 to 31.3); lower BMD/quartile 2, HR = 11.2 (3.1 to 41.0); lower BMD/quartile 3, HR = 12.7 (3.5 to 45.9); and lower BMD/quartile 4, HR = 22.3 (5.8 to 86.3). (Data from Arasu A, Cawthon PM, Lui LY, et al. Serum sclerostin and risk of hip fracture in older Caucasian women. *J Clin Endocrinol Metab* 2012;97:2027-32.)

When sclerostin is low, it would be expected that BMD and bone formation would be high and vice versa. Glucocorticoid-induced osteoporosis fits this model with high sclerostin, low bone formation, and low BMD. Postmenopausal women have higher sclerostin than premenopausal women do, but with high bone formation markers and low BMD. With estrogen therapy there is a decrease in sclerostin and a relative decrease in bone formation.⁴¹ In a study of immobilization in young men, sclerostin was increased in response to 90 days of bed rest. Bone resorption but not bone formation was increased with a decrease in parathyroid hormone and BMD.⁴⁷

Preliminary data are inconclusive, and this is an area for future development. Regulators of bone turnover, including sclerostin and Dkk-1, are promising targets for anabolic therapies for metabolic bone disease. Clinical trials are evaluating antibodies against sclerostin and Dkk-1 for the treatment of bone loss.⁴⁸

Periostin

Periostin is an osteoblast-specific factor that was renamed periostin because of its preferential location in the periosteum. Periostin has a role in bone biology, possibly in the regulation of bone formation.⁴⁹ It is expressed in collagen-rich fibrous connective tissues such as bone, heart valves, tendons, and periodontal ligaments, as well as by some tumors. The role of periostin in connective tissue disease has yet to be determined. In metastatic bone disease, periostin is increased in breast and prostate cancer with bone metastases.⁵⁰ Periostin could be an early marker of bone metastasis or periosteal apposition, but further studies are required.

Pentosidine

Advanced glycation end products (AGEs) are formed by nonenzymatic glycosylation of protein amino groups. AGEs have been observed in bone tissue and associated with a decrease in the mechanical properties of bone. Pentosidine is one of the most studied AGEs; it forms cross-links between collagen molecules, which potentially alters their structure and function. Pentosidine increases with aging, and high levels of pentosidine have been identified as a risk factor for fracture in older adults with diabetes.⁵¹ However, pentosidine is not specific to bone tissue, and further identification of tissue-specific AGEs would be beneficial in studying their effects on the structural properties of bone.

VARIABILITY IN BIOCHEMICAL MARKERS OF BONE TURNOVER

Automated assays are now available for many of the established bone markers. They provide fast, high-volume sample throughput with high analytic precision.^{52,53}

Sources of variability in the measurement of biochemical markers of bone turnover should be considered and controlled,^{54,55} including preanalytic and analytic variability.⁵⁶ There are both modifiable and nonmodifiable sources of variability, some examples of which are presented in Table 200.1. Preanalytic variability includes uncontrollable factors such as age, gender, ethnicity, geographic location, medications, diseases, and other conditions that can affect bone markers such as pregnancy, immobilization, and fracture.⁵⁷⁻⁶¹ These factors cannot be controlled; however, it is important to be aware of their influence on clinical interpretation of bone turnover marker results.

Sources of preanalytic variability that are controllable include circadian rhythm, effect of meals, menstrual cycle, diet, and exercise.^{62,63} These factors can be controlled by standardization of timing and conditions for collection of samples. Bone markers decrease following a meal, which can be controlled by collecting samples following an overnight fast.^{64,65}

Analytic variability should be minimized by controlling for parameters identified in assay protocols such as correct sample collection, processing, and storage and assay conditions such as temperature monitoring.⁶⁶

CLINICAL UTILITY OF BIOCHEMICAL MARKERS OF BONE TURNOVER

Bone markers are useful tools for understanding the mechanism of action of therapeutic agents on bone in clinical trials. In a clinical setting they are useful for monitoring response to treatment and identifying possible causes of secondary osteoporosis (e.g., myeloma, chronic kidney disease). Bone markers do not have a role in the diagnosis of osteoporosis; this is routinely assessed by measuring BMD with dual-energy x-ray absorptiometry.

TABLE 200.1

Sources of preanalytic variability to be considered for interpretation of results from bone turnover marker (BTM) measurements

Source of variability	Comment
Uncontrollable	
Age, pubertal stage	High BTMs in children. Use appropriate reference interval
Gender	Use male/female reference intervals
Geographic location	Use appropriate reference interval
Ethnicity	Use appropriate reference interval
Menopause	Increased BTMs
Oral contraceptive	Lower values of BTMs
Pregnancy and lactation	Elevated BTMs
Recent fracture	BTMs elevated for up to 1 year
Metabolic bone disease	Usually cause an increase in BTMs
Renal/hepatic function	Increase in BTMs
Medications	Record the medical/drug history
Controllable	
Circadian rhythms	Collect samples at the same time of day during each visit
Meals	Because BTMs decrease after food, take fasting samples
Diet	Because BTMs decrease after Ca supplementation, take fasting samples
Seasonal	Repeat visits in the same season
Exercise	Effect is dependent on type and duration
Menstrual cycle	Collect samples in the early phase of the cycle

Proposed applications of biochemical markers of bone turnover include (1) prediction of increased risk for fracture, (2) prediction of whom will benefit from treatment, (3) assessment of the efficacy of treatment, and (4) promotion of adherence to treatment.

Markers of bone turnover for prediction of bone loss and fracture risk

There is a strong association between bone density measurements and risk for fracture; however, assessment of fracture risk by measurement of BMD lacks sensitivity because up to half of patients who sustain a nonvertebral fracture do not have osteoporosis (BMD T-score of -2.5 or less).^{67,68}

Bone markers are elevated in metabolic bone diseases and other conditions associated with accelerated bone loss. Bone turnover is increased in postmenopausal women and is higher in those with lower bone mass.^{69,70} Although high levels of bone markers are associated with accelerated rates of bone loss, the predictive value at an individual patient level is uncertain.⁷¹ It is possible that the deterioration in bone architecture caused by increased bone turnover may have a greater effect on bone strength and fracture risk than the decrease in bone mass does. Vasikaran and colleagues reviewed prospective studies that examined the association of bone turnover markers with subsequent fracture.¹⁷ Some of the limitations identified included inconsistent results for individual bone markers, different methodologies and sample collection procedures, use of multiple statistical approaches, and heterogeneity in the fracture types identified.

Bone markers for identification of patients who will benefit from treatment

Bone markers may be useful for identifying patients who are the most likely to have the best response to treatment. Some studies have shown that participants with higher pretreatment bone turnover markers have a greater increase in bone density in response to treatment with antiresorptive agents.^{72,73} The Fracture Intervention Trial reported that participants treated with alendronate who had higher pretreatment bone formation markers had a greater reduction in nonvertebral fractures than did those with lower bone turnover.⁷⁴ However, the association between pretreatment bone markers and response to treatment is modest and variable. The use of bone markers to identify patients for specific types of treatment warrants further study.

Fig. 200.4 Percent change from baseline in bone turnover markers—(a) C-terminal telopeptide of type I collagen (CTX); (b) PINP; (c) tartrate-resistant acid phosphatase 5b (TRAcP-5b); (d) bone alkaline phosphatase (BALP)—in a randomized trial of treatment with denosumab (FREEDOM Trial). The horizontal line represents no change, and each point and error bar represent the median percent change and interquartile range, respectively. Samples were measured before the next injection, with the exception of months 1 and 36, at which time the dose was not administered. * $P < .000$. (From Eastell R, Christiansen C, Grauer A, et al. Effects of denosumab on bone turnover markers in postmenopausal osteoporosis. *J Bone Miner Res* 2011;26:530-7.)

Bone markers for monitoring treatment of bone disease

The aim of treatment of metabolic bone disease is to reduce the risk for fragility fractures.⁷⁵ To monitor treatment efficacy, bone density measurements have been used as surrogate markers for fracture in many clinical trials. It is assumed that a change in bone density brought about by treatment reflects a change in the clinical endpoint, occurrence of fracture.

The change in BMD in response to treatment is relatively small, and in individual patients in clinical practice it is necessary to wait at least 2 years to determine whether a treatment is effective. Biochemical markers of bone turnover generally respond more rapidly and with greater magnitude of change than BMD does.⁷⁶ This is useful for managing the treatment of patients, particularly those who show no change in bone markers. Good adherence to risedronate treatment was associated with greater changes in bone markers and a reduction in fracture risk.⁷² The influence on adherence to treatment by feedback of information to patients regarding the change in bone markers is inconclusive.⁷⁷⁻⁷⁹

A modest or no change in bone markers with osteoporosis treatments may identify poor compliance or, less commonly, a lack of response. Other conditions may be the cause of persistently elevated bone turnover markers, such as fracture or comorbid conditions.

Response of bone markers to treatment

Clinical trials of antiresorptive treatments of postmenopausal osteoporosis have shown bone turnover markers to decrease after the start of treatment. The aim of treatment is to reduce bone turnover to the lower half of the premenopausal reference range.⁸⁰ Those in the lower half of the reference range have the lowest risk for fracture. The magnitude, onset, and duration of response are dependent on the study population, treatment, and bone marker measured. Treatment with bisphosphonates prompts a rapid decrease in bone resorption markers. Alendronate treatment causes a significant decrease in bone resorption within 3 months, followed by a decrease in bone formation around 6 to 12 months.^{21,81,82} Similar decreases have been reported in men.⁸³⁻⁸⁷ Bone resorption markers remain suppressed for up to 5 years after cessation of alendronate treatment.⁸⁸

Intravenous bisphosphonates such as zoledronic acid produce a more rapid decrease in bone turnover, within 1 month for bone resorption and 3 months for bone formation.^{89,90} Denosumab is a monoclonal antibody that mimics OPG by targeting RANKL to inhibit bone loss. Denosumab treatment produces a large and rapid decrease in bone resorption followed by a slower decrease in bone formation (Fig. 200.4).^{91,92}

Bone markers have also been used to study the anabolic effect of teriparatide. The bone formation marker PINP doubled after 1 month of treatment and reached a maximum response after 6 months.^{93,94} These changes were more dynamic than those of other bone formation markers.

Bone markers can provide useful information in drug development by providing data on different dosing regimens. Antiresorptive treatments such as the bisphosphonate ibandronate produce a dose-dependent decrease in bone resorption,⁹⁵ whereas anabolic agents induce increases in bone formation markers.⁹⁶ Cathepsin K inhibitors suppress bone resorption by a greater magnitude than they do bone formation.⁹⁷ It has been suggested that bone markers are possible candidates as surrogate endpoints for fracture in clinical trials of osteoporosis.⁹⁸

SUMMARY

Well-established markers of bone turnover that have proved useful in monitoring treatment are available. Bone markers may be useful to establish an optimal dose for new treatments of osteoporosis. More work is needed to standardize assays so that results can be compared between studies and centers. Further data are needed on the clinical utility of bone markers. New markers are emerging that may provide a better understanding of the local regulation of bone turnover and changes in the quality of bone. Further information on the circulating molecular forms and kinetics of these analytes is required.

Management of osteoporosis

■ CHAD L. DEAL ■ ABBY G. ABELSON

- A woman's lifetime risk for fracture is 40%, so strategies to evaluate and treat women at risk are critical to reduce fracture burden.
- Effective evaluation and treatment include a workup for secondary causes of low bone mass, lifestyle modification, fall prevention, calcium and vitamin D supplementation, and when appropriate, therapy with an antiresorptive or anabolic agent.
- Antiresorptive agents include the bisphosphonates, which are available in oral and intravenous forms; denosumab, a monoclonal antibody against RANKL; raloxifene, an estrogen agonist-antagonist; and strontium ranelate, available outside the United States. The only anabolic agent approved in the United States is teriparatide (recombinant human parathyroid hormone 1-34).
- The appropriate duration of antiresorptive therapy is an important issue that should be decided by weighing the benefits of fracture prevention and potential long-term side effects.

INTRODUCTION

A comprehensive management plan for osteoporosis should include assessment of fracture risk, interventions that reduce the risk for future fractures, and treatment of patients with acute fractures. Assessment of fracture risk is critical for making cost-effective treatment decisions in individual patients. A woman's lifetime risk for fracture is 40% and for hip fracture, 16%.¹

Low bone mass increases fracture risk; risk factors that are independent of bone mass also contribute to fracture risk, including older age and falls. This chapter focuses on the management of osteoporosis and covers guidelines for treatment; pretreatment evaluation, including exclusion of secondary causes of low bone mass; nonpharmacologic therapies, including exercise; fall prevention; calcium and vitamin D supplementation; drug therapies; emerging therapies; and treatment of fractures. Identification of subjects at risk for fracture based on bone mineral density (BMD) and clinical risk factors is discussed in Chapter 198.

RECOMMENDATIONS FOR TREATMENT

In February 2008 the World Health Organization (WHO) published FRAX, a fracture risk assessment tool (<http://www.shef.ac.uk/FRAX/>), and the National Osteoporosis Foundation (NOF) released new guidelines for the prevention and treatment of osteoporosis in the United States. Previous guidelines from the NOF and American Association of Clinical Endocrinologists were based on previous fracture, BMD T-score, and risk factors but were limited in that they addressed only postmenopausal women, not men; lacked weighting of risk factors; did not adequately account for the effect of age on risk for fracture; and expressed future fracture risk as increased relative, not absolute risk. Because at least 50% of all fractures occur in individuals who have low BMD but not osteoporosis, the addition of risk factors to BMD is a method for selecting higher-risk patients within this category who need treatment.

The 2008 NOF guidelines ("Clinician Guide to Prevention and Treatment of Osteoporosis," available at http://www.nof.org/professionals/Clinicians_Guide.htm) are based on the FRAX calculator, which expresses fracture risk as a 10-year probability of fracture and uses an economic analysis for cost-effective treatment thresholds.²

Treatment is recommended if the BMD T-score is less than -2.5 at the hip or lumbar spine, if the patient has had a hip or vertebral fracture, or if the T-score is between -1.0 and -2.5 at the hip or spine and the 10-year fracture risk by FRAX is 3% or higher for hip or 20% or higher for a major osteoporosis-related fracture (humerus, forearm, hip, or clinical vertebral fracture). The WHO FRAX tool allows individual assessment for ethnicity in the United States and in more than 40 country-specific databases and calculates fracture risk on the basis of gender, height, previous fragility fracture as an adult, parental history of hip fracture, glucocorticoid use, rheumatoid arthritis, secondary osteoporosis, and alcohol use. The NOF guidelines and FRAX are applicable to previously untreated postmenopausal women and men older than 50 years (Fig. 201.1).

The FRAX model has limitations.³ Nonetheless, FRAX and the 2008 NOF treatment guidelines for osteoporosis offer a significant advance by providing health care personnel with treatment recommendations on the basis of BMD (or body mass index if BMD has not been measured) and clinical risk factors and by predicting absolute, not relative fracture risk.

EVALUATION FOR SECONDARY OSTEOPOROSIS

Management of a patient with osteoporosis requires attention to possible secondary causes. Many individuals with low bone mass have diseases (Table 201.1) or take medications that affect bone metabolism (Table 201.2). Switching medications to alternatives that do not adversely affect bone quality or providing preventive therapy should be considered. Laboratory investigation in patients with low bone mass is recommended since up to 50% have underlying disorders such as vitamin D deficiency or hypercalciuria. Routine laboratory tests to identify common causes of secondary osteoporosis include a complete blood count, sedimentation rate, chemistry profile, 25-hydroxyvitamin D, thyroid-stimulating hormone, parathyroid hormone (PTH), and 24-hour urine for measurement of calcium excretion (Box 201.1). Correction of the underlying cause may have a substantial impact on BMD and fracture risk and needs to be done before institution of any pharmacologic therapy.

TREATMENT: NONPHARMACOLOGIC THERAPY

This section focuses on evidence-based approaches or, in the absence of evidence, general consensus.

Patient and physician education

Education on risk for falls, exercise programs, dietary advice including adequate calcium and vitamin D intake, and other lifestyle modifications are an important first step for those at risk. Assessment of propensity for falls and modification of such risk factors through effective intervention when possible should be undertaken. Use of assistive devices and a multidisciplinary team approach for prevention of falls have been shown to be efficacious and should be considered for appropriate individuals. Such measures, coupled with careful observation and reassurance, may be all that is necessary for many individuals with low BMD who are thought to have low absolute risk for fracture and who do not have osteoporosis or a previous fracture.

Exercise

The molecular mechanisms that result in skeletal mechanotransduction are complex. Regular exercise increases bone strength by creating small gains in bone mass.⁴

TABLE 201.1
Secondary causes of low bone mass

Category	Specific examples
Inflammatory diseases	Rheumatoid arthritis Ankylosing spondylitis Psoriatic arthritis
Malabsorption syndromes	Celiac disease Short bowel syndrome Cystic fibrosis
Endocrine diseases	Hypogonadism Hyperthyroidism (exogenous and endogenous)
Deficiency states	Vitamin D deficiency Malnutrition Excessive weight loss
Renal diseases	Renal insufficiency Renal osteodystrophy Renal tubular acidosis Idiopathic hypercalciuria
Bone marrow disorders	Multiple myeloma Thalassemia
Genetic diseases	Osteogenesis imperfecta Ehlers-Danlos syndrome Turner syndrome
Prolonged immobilization	Stroke Quadriplegia Space flight

TABLE 201.2
Medications known to cause or accelerate bone loss

Category	Name
Steroids	Glucocorticoids
Endocrine/hormonal therapies	Depo-Provera, GnRH analogues, LHRH analogues, excessive thyroid hormone replacement
Diuretics	Furosemide
Chemotherapy	Cyclosporine, methotrexate, tacrolimus
Transplant	Cyclosporine
Aromatase inhibitors	Exemestane, anastrozole
Seizure medications	Phenytoin, phenobarbital
Psychotropic	Lithium, neuroleptics
Other	Heparin

GnRH, gonadotropin-releasing hormone; LHRH, luteinizing hormone-releasing hormone.

BOX 201.1 RECOMMENDED LABORATORY INVESTIGATIONS FOR INDIVIDUALS WITH OSTEOPOROSIS

Recommended screening in all patients

Serum calcium, albumin, phosphorus*^{†,‡,§}
Serum creatinine*^{†,‡,§}
Liver function tests*
Bicarbonate*
Complete blood count*
24-Hour urinary calcium level*^{†,‡,§}
25-Hydroxyvitamin D level*^{†,‡,§}
Thyroid-stimulating hormone level*^{†,‡,§}

Other testing if appropriate

Biochemical markers of bone turnover*^{†,‡,§}
Cortisol levels*[†]
Protein electrophoresis*^{†,§}
Parathyroid hormone level*^{‡,§}

Exercise in children, especially when combined with calcium intake, appears to be most effective before attainment of peak bone mass. Moderate, regular weight-bearing exercise is essential for skeletal health, both for direct effects on bone strength and for prevention of falls. Intensive regular weight-bearing exercise increases BMD, at least transiently, although the effect tends to wear off after cessation of such a regimen. Devices that deliver a specific mechanical stimulation (vibration plates) may also have a similar effect.⁵

Exercises to increase muscle strength result in better conditioning and balance, thereby helping reduce risk for falls. Although regular weight-bearing exercise has been shown to increase or preserve BMD in young and middle-aged individuals, exercise alone does not prevent postmenopausal bone loss. Combining exercise programs with calcium supplementation or other therapeutic interventions may be more effective in maintaining bone mass than either intervention alone.⁶

Smoking, alcohol, and caffeine

Smoking is directly toxic to bone cells, and population studies have shown that smokers have lower BMD, a greater annual rate of bone loss, and a higher prevalence of osteoporosis than nonsmokers do. Current smokers have been shown to have an increased risk for hip fracture relative to never smokers. Although limited data are available on the benefits of smoking cessation, discontinuation of tobacco use has resulted in favorable effects on bone metabolism in some small trials. The Nurses' Health Study found that fracture risk fell, but only after 10 or more years of abstinence from smoking.⁷

Although alcohol in moderation may have a positive effect on BMD, three or more drink equivalents per day should be discouraged given its association with an increased propensity for falls and risk for fracture. A meta-analysis demonstrated a J-shaped relationship between alcohol consumption and risk for hip fracture, with persons consuming less than one or more than two drinks per day having a higher risk for hip fracture.⁸

Excessive caffeine use has been associated with decreased intestinal calcium absorption and lower dietary calcium intake. Because caffeine may induce hypercalciuria and has been linked to an increased risk for fracture, moderation or cessation of intake is required in those at risk. However, all studies linking caffeine intake as a risk factor for osteoporosis have involved populations with suboptimal calcium intake.

Calcium and vitamin D

Recent studies have resulted in conflicting recommendations about the optimal intake of calcium and vitamin D. The Institute of Medicine (IOM) emphasized the limitations of the existing studies on the benefits and risks of calcium and vitamin D supplementation (see Chapter 203 for current IOM recommendations).⁹

A 2011 meta-analysis conducted for the U.S. Preventive Services Task Force demonstrated the complexity of the analyses, with the impact of

TABLE 201.3
Recommended supplementation of calcium and vitamin D

Individual age categories	Elemental calcium	Vitamin D*
Birth to 6 mo	400 mg	200 IU
6-12 mo	600 mg	200 IU
1-10 yr	800 mg	200 IU
11-24 yr	1200-1500 mg/day	400 IU
Women and men 25-65 yr: premenopausal or postmenopausal taking estrogen	1000 mg/day	400-600 IU
Postmenopausal woman, no estrogen	1500 mg/day	400-600 IU for men and women >65 yr
Pregnant and lactating women	1200-1500 mg/day	400 IU
National Osteoporosis Foundation guidelines	1200 mg	800-1000 IU

*These recommendations are guidelines and may be sufficient for healthy individuals with normal 25-hydroxyvitamin D levels. In many circumstances, however, they are insufficient.

supplementation on fracture risk being smaller in community dwellers and in institutionalized individuals.¹⁰

Current recommendations for supplementation of calcium and vitamin D are presented in Table 201.3; however, in some instances larger doses of vitamin D may be necessary. Assessment of vitamin D status by measuring serum 25-hydroxyvitamin D levels is required before initiation of pharmacologic therapy.¹¹

Serum 25-hydroxyvitamin D levels should be rechecked after about 8 to 12 weeks of replacement therapy.¹²

Adequate correction of vitamin D deficiency (normal vitamin D, alkaline phosphatase, PTH, and 24-hour urine calcium) should be undertaken before institution of pharmacologic therapy for osteoporosis. Striking gains in BMD may be seen within months in individuals in whom severe deficiency is corrected. Skeletal muscle also has receptors for vitamin D, and evidence suggests that elderly institutionalized subjects randomized to supplemental vitamin D significantly lower their risk for falls. In some situations such as renal osteodystrophy, more extensive evaluation and complex replacement therapy with calcium and vitamin D may be necessary (see Chapter 205).

Both calcium and vitamin D stabilize BMD, have favorable effects on biochemical markers of bone turnover, and reduce the risk for fracture. Chapuy and colleagues¹³ demonstrated in two large randomized, placebo-controlled trials that elderly institutionalized individuals with osteoporosis randomized to a combination of calcium and vitamin D supplementation significantly reduced their risk for vertebral, nonvertebral, and hip fractures.

Recent studies have questioned the true efficacy of this therapy in some populations; however, it is unclear whether adherence was adequate in these studies.¹⁴

A meta-analysis of the effect of oral vitamin D on prevention of nonvertebral fractures concluded that its efficacy for fractures is dose dependent, with higher doses reducing fractures by at least 20%.¹⁵

Prevention of falls

Almost a third of persons older than 70 years will sustain a fall each year, with higher numbers being reported in women, older individuals, and nursing home residents. Falls are a major source of morbidity and increased mortality, and about 5% result in a fracture. Nursing home residents are three times more likely to fall, in part because of their increased frailty, and they sustain a higher number of hip fractures and have a poorer prognosis after fracture than do community dwellers. In the Dubbo Osteoporosis Epidemiology Study, falling in the previous year was the factor that most highly correlated with risk for incident hip fracture in more than 1600 nonosteoporotic men and women observed for 15 years (hazard ratio [HR], 1.9 and 2.1, respectively).¹⁶

Most falls are predictable, with readily identifiable risk factors (Box 201.2). Studies have shown that risk for falls is related to a history of falls; use of medications or conditions that predispose to falls, including cognitive, visual, or auditory impairment; decreased muscle strength; increased body sway; and poor balance. Such conditions are more prevalent in older

BOX 201.2 FACTORS PREDISPOSING TO FALLS

Postural hypotension
Stairs, restraints, lack of support rails
Poor lighting
Delirium
Wet floors or uneven surfaces

individuals, and the propensity to fall increases as the number of risk factors rises.^{17,18}

Thorough evaluation of the risk for falls and careful clinical assessment of medications and conditions that may contribute to such risk or bone loss can readily be performed in the office by a trained health care provider. Dissemination of evidence about fall prevention, along with interventions to affect clinical practice, may reduce fall-related injuries. Assessing all factors that influence the propensity for falls may be better accomplished with more comprehensive methods, and a multidisciplinary team approach can be effective.¹⁹

Controlled studies evaluating tai chi have shown that this particular type of exercise reduces falls and fear of falling and improves muscle strength and activity in elderly persons.²⁰

Hip pads and other assistive devices

Hip protectors have been shown to prevent hip fractures in compliant subjects at significant risk for falling.²¹ A study involving 18 nursing homes randomized patients to hard or soft hip protectors and showed a 60% reduction in hip fractures in patients using protectors.²² However, not all devices are the same and not all studies show an effect. Although compliance is poor and the effectiveness remains unclear, high-risk individuals who wear hip pads may reduce their risk for proximal femoral fracture. Given the benign nature of this intervention, it is worth considering in elderly osteoporotic patients at increased risk for falls.

PHARMACOLOGIC INTERVENTIONS

Hormone replacement therapy

The major cause of postmenopausal osteoporosis is estrogen deficiency. With declining levels of estrogen in postmenopausal women, bone turnover increases, the rate of bone resorption exceeds the rate of bone formation, and bone density decreases.²³

A meta-analysis of 57 randomized placebo-controlled trials reported significantly increased bone density in patients receiving hormone therapy.²⁴

Estrogen therapy decreased the risk for hip fractures by 25% to 30% and the risk for vertebral fractures by approximately 50% in observational studies.²⁵

In the Women's Health Initiative (WHI) trial in which women unselected for osteoporosis were randomized to treatment with estrogen plus progestone or placebo, the incidence of all fractures decreased by 24% and hip fractures were reduced by 33% when compared with placebo.²⁶

In the WHI trial of unopposed estrogen in postmenopausal women with a previous hysterectomy unselected for osteoporosis, the women receiving unopposed estrogen demonstrated a reduction in the risk for hip fracture by 39% and risk for vertebral fracture by 38%. The reduction in fracture risk associated with hormone therapy diminishes after it is stopped. In the National Osteoporosis Risk Assessment observational cohort, women who used hormone therapy for 5 to 10 years after menopause and then

discontinued its use had no greater bone density at the heel or radius at the age of 70 than did women who never used hormone therapy.²⁷

Worldwide patterns of estrogen use have changed radically since publication of results from the WHI raised concern regarding increased risk for cardiovascular disease, stroke, pulmonary embolism, and breast cancer with estrogen.²⁸

Several randomized controlled trials (RCTs) have documented additional risks associated with hormone therapy, including stroke and venous thromboembolism and possibly gallbladder disease.²⁹⁻³¹

The effect of hormone therapy on risk for cardiovascular disease is currently controversial because the differences observed in the results of previous randomized trials may be related to the type of progestin used in the trials.³²

Additional studies on cognitive dysfunction, ovarian cancer, and other conditions have yielded inconsistent results. A recent statement on menopausal hormone therapy for the U.S. Preventive Services Task Force recommended against the use of combined estrogen and progesterone for prevention of chronic health conditions in postmenopausal women who have undergone hysterectomy.³³

Estrogen agonist-antagonists

Although estrogen therapy has been demonstrated to increase BMD and decrease fracture risk, recognition of the risks and toxicities of estrogen therapy has directed research on compounds that can selectively act as either agonists or antagonists on various estrogen target tissues. Estrogen agonist-antagonists are compounds that possess tissue specificity and bind to estrogen receptors. These agents represent a group of compounds that can inhibit bone resorption through mechanisms similar to estrogens without stimulating other tissues such as breast or uterine tissue.³⁴ The mechanisms for these differential effects on estrogen receptors that result in tissue specificity can be explained by differential gene expression in a given target tissue, differential estrogen-receptor conformation on ligand binding, and differential expression and binding of coregulator proteins to the estrogen receptor.

Several agents such as clomiphene and tamoxifen were developed for the treatment of nonskeletal conditions. Tamoxifen, for example, is currently used for the treatment and prevention of breast cancer and acts as an estrogen receptor antagonist in breast tissue, but it was recognized to possess estrogen agonist effects on the endometrium and weak estrogen agonist activity in bone, although the increases in bone density in patients treated with tamoxifen are minimal (Table 201.4) and the effects on fracture risk are variable.³⁵⁻⁴³

Raloxifene was specifically developed to have antiresorptive effects on bone in postmenopausal women. A reduction in risk for vertebral fractures was demonstrated in the Multiple Outcomes of Raloxifene Evaluation (MORE) study. In this study, raloxifene was shown to decrease markers of bone turnover and increase bone density at several skeletal sites, including the spine and femoral neck. The incidence of vertebral fracture decreased

by 30% in subjects with a prevalent fracture and by 55% in subjects without a prevalent fracture. However, the incidence of nonvertebral fractures, including hip fracture, did not differ significantly between the treatment and placebo groups. A *post-hoc* analysis from MORE show a decreased risk for nonvertebral fracture at 3 years only in subjects with severe vertebral fractures (semiquantitative grade 3) at baseline.⁴⁴

The women receiving raloxifene had a higher risk for venous thromboembolism, leg cramps, and hot flashes than did those given placebo. Of interest, women in the treatment group exhibited a lower incidence of invasive breast cancer (relative risk, .4; $P < .001$).⁴⁵

The Continuing Outcomes Relevant to Evista (CORE) trial assessed the effects of raloxifene on breast cancer for 4 additional years beyond the original 4-year MORE trial. After 8 years of follow-up, the risk for invasive breast cancer was reduced by 66% in women treated with raloxifene. The incidence of nonvertebral fractures was similar in the placebo and raloxifene groups.⁴⁶

Raloxifene is approved for reduction in risk for invasive breast cancer in postmenopausal women with osteoporosis and in postmenopausal women at high risk for invasive breast cancer.⁴⁷ Comprehensive reviews of the use of raloxifene for prevention of breast cancer and clinical efficacy and safety have been published.^{48,49}

The third-generation estrogen agonist-antagonists lasofoxifene and bazedoxifene are approved in the European Union but not in the United States for the treatment of osteoporosis in women at increased risk for fracture.⁵⁰ A 5-year trial of lasofoxifene demonstrated a 31% and 42% reduction in vertebral fractures (dose, 0.25 and 0.5 mg). The 0.5-mg dose also reduced the risk for nonvertebral fractures at 5 years ($P = .002$).⁵¹

A 3-year trial of bazedoxifene 20 or 40 mg, raloxifene 60 mg, or placebo showed a 42% reduction in new vertebral fractures with bazedoxifene 20 mg and raloxifene. The treatment effect of both drugs was similar in subjects with or without prevalent fractures. A *post-hoc* analysis in women with a femoral neck T-score of -3.0 or lower and moderate or severe vertebral fractures found a lower incidence of nonvertebral fractures with bazedoxifene than with raloxifene or placebo (44% and 50% reduction, $P = .05$ and $.02$, respectively).⁵²

Calcitonin

Calcitonin, a naturally occurring 32-amino acid polypeptide hormone produced by parafollicular "C" cells of the thyroid, pituitary, and neuroendocrine system, is secreted in response to high plasma ionized calcium levels. Salmon calcitonin, administered parenterally or as a nasal spray, is used as treatment of postmenopausal osteoporosis, as well as Paget disease of bone and hypercalcemia. It is an antiresorptive agent that inhibits bone resorption by binding to receptors on osteoclasts. A number of studies suggest that it is effective for spinal osteoporosis by maintaining or slightly increasing BMD, and one study showed that intranasal calcitonin at a dose of 200 IU/day reduced incident vertebral fractures in women with prevalent vertebral fractures.⁵³

TABLE 201.4

† $P < .005$ for comparison with placebo.

Calcitonin may have analgesic effects on bone pain in patients with osteoporosis, which has been noted in clinical trials and has led to a reduction in conventional analgesia and a decrease in disability.⁵⁴

Bisphosphonates

Bisphosphonates are the pharmacologic agents most commonly used for the treatment of osteoporosis. Both oral and intravenous preparations of bisphosphonates are currently approved by the Food and Drug Administration for the prevention and treatment of osteoporosis. Their efficacy is based on their ability to both bind avidly to bone and inhibit osteoclast function. The relative potency of the different bisphosphonates is a function of differences in side chain structure among the compounds.⁵⁵

Bisphosphonates are stable synthetic analogues of pyrophosphate (Fig. 201.2). Their primary effect is to suppress osteoclast-mediated bone resorption. They bind avidly to bone, a property that is primarily related to the R1 side chain (Table 201.5) (an OH group for nitrogen-containing bisphosphonates), which functions as a “bone hook.” The R2 side chain determines the compound’s potency as an antiresorptive agent and contains the nitrogen group common to all potent bisphosphonate compounds. The nitrogen-containing bisphosphonates (alendronate, risedronate, ibandronate, pamidronate, and zoledronate) interfere with the mevalonate pathway by inhibiting the enzyme farnesyl pyrophosphate (Fig. 201.3). This prevents protein prenylation, or attachment of a lipid anchor in the membrane, which inhibits osteoclast recruitment, differentiation, formation of the ruffled border, and acid production and induces apoptosis.

Suppression of osteoclasts decreases bone turnover, thereby reducing the number and activity of bone-remodeling units (BMUs). Bone remodeling sites are a source of trabecular perforations, as well as microcracks and stress risers, weak areas that can propagate in bone and result in increased fragility and fractures. The decrease in bone resorption with bisphosphonate therapy occurs within 1 month. Because of the coupling of formation and resorption, inhibition of resorption results in a decrease in bone formation. Inhibition of resorption before formation allows the “remodeling space,” or the cavities created by BMUs, to fill, which increases bone mass. The increase in bone mass created by this uncoupling of bone resorption and formation results in a brisk rise in BMD in the first 1 to 2 years of therapy. Subsequent increases in BMD occur at a slower rate, approximately 0.8% per year through 10 years for alendronate, and are the consequence of an increase in matrix mineralization, a result of the decrease in turnover that allows

more complete secondary mineralization of bone, as well as a decrease in cortical porosity.

It is estimated that approximately 25% of the observed reduction in fracture risk is related to increases in BMD. Other factors that may be important include decreased bone turnover, altered microarchitecture, changes in mineralization, and other cellular effects.

Pharmacologic properties

Orally administered bisphosphonates are poorly absorbed, with less than 0.7% of the administered dose being absorbed into the bloodstream. Food and liquids (except plain water) inhibit bisphosphonate absorption within the first 120 minutes after dosing. Absorption of alendronate is 40% to 50% less when food is consumed 30 to 60 minutes after a dose than when it is consumed 120 minutes after dosing. A meal 2 hours before dosing also results in poor absorption, so it is recommended that these agents be taken after an overnight fast with no food or liquid other than water for a minimum of 30 minutes. For alendronate, approximately 50% of the dose is retained in the skeleton and the remainder is excreted unchanged in urine. Patients with impaired renal function and creatinine clearance lower 30 mL/min retain a greater amount of the dose in the skeleton. This could reduce turnover to a degree that would impair the ability to repair microdamage. Analysis of risedronate in patients with various degrees of renal impairment concluded that no adjustment in dose was needed with a creatinine clearance higher than 30 mL/min.⁵⁶

Similar data for other orally administered nitrogen-containing bisphosphonates, including alendronate and ibandronate, are reviewed in Chapter 205. Intravenous zoledronic acid is contraindicated in patients with a creatinine clearance lower than 35 mL/min.

After 3 months of oral bisphosphonate therapy, bone turnover is reduced to the middle to lower range of normal premenopausal turnover. With continued treatment and incorporation into the skeleton, no further reduction in turnover occurs, thus suggesting that the accumulated drug is buried in bone and becomes inactive. In the vast majority of patients, bone turnover is not reduced to such a level that accumulation of microdamage occurs, which might increase risk for fractures. Histomorphometric data sometimes show marked inhibition of skeletal turnover with these drugs, but biopsy data in a small number of patients treated for up to 10 years with alendronate and 5 years with risedronate are available and do not show significant

Fig. 201.3 Nitrogen-containing bisphosphonates such as risedronate sodium, zoledronic acid, disodium pamidronate, alendronic acid, and ibandronic acid work predominantly by inhibiting the enzyme FPPS, which catalyzes a step in the mevalonate pathway and inhibits protein prenylation. Protein prenylation involves the transfer of a farnesyl or geranylgeranyl isoprenoid lipid group onto the C-terminus of small GTPases. GTPases are critical for osteoclast proliferation, apoptosis, membrane ruffling, and membrane trafficking. Loss of these prenylated proteins in cell membranes results in loss of osteoclast function. FPP, farnesyl pyrophosphate; FPPS, farnesyl pyrophosphate synthase; GGPP, geranylgeranyl diphosphate; GTPase, guanine triphosphatase; HMG-CoA, hydroxyl-3-methylglutaryl coenzyme A.

accumulation of microdamage. Bone biopsy specimens from alendronate-treated patients versus placebo-treated patients demonstrate decreased cortical porosity (7.5% with placebo and 4% with alendronate) and increased uniformity of mineralization with a slight increase in mineral per unit volume.⁵⁷

Because the cortical shell provides most of the bending strength of bone, this observed reduction in porosity could account for a portion of the anti-fracture efficacy of alendronate.

Clinical trials

Clinical trial experience with bisphosphonates is summarized in Table 201.6. Bisphosphonates decrease fracture risk in patients at high risk for fracture, including those with prevalent vertebral fractures or osteoporosis.

Etidronate

Etidronate is the oldest bisphosphonate in use and is approved for the treatment of postmenopausal osteoporosis in numerous countries, though not in the United States. Trials have demonstrated a reduction in the incidence of vertebral fractures in high-risk populations.⁵⁸ The weight of the evidence supports its efficacy in reducing vertebral fractures in patients with osteoporosis; a meta-analysis reported a 37% reduction in vertebral fractures.⁵⁹

Etidronate is given at a dose of 400 mg/day for 14 days every 3 months instead of continuously to avoid a mineralization defect. It has not been shown to reduce the incidence of nonvertebral fractures, including hip fractures.

Alendronate

Alendronate was approved for the prevention and treatment of osteoporosis in the United States in 1995. It was shown to increase BMD in a dose-dependent fashion in postmenopausal women without osteoporosis. Current practice is to use weekly doses of 35 or 70 mg for prevention and treatment, respectively, which were shown to result in increases in BMD equivalent to 5 or 10 mg/day. In postmenopausal women with low BMD (femoral neck T-score of -1.6 and below) and prevalent vertebral fractures (Fracture Intervention Trial, Vertebral Fracture Arm [FIT 1]) treated for 3 years, alendronate significantly reduced vertebral, hip, and wrist fractures by approximately 50% and multiple vertebral fractures by 89%.^{60,61}

In women without vertebral fractures but with low BMD treated for 4 years (FIT Clinical Fracture Arm [FIT 2]), a 44% reduction in vertebral fractures was noted ($P = .001$).⁶²

A preplanned, *post-hoc* analysis of patients with either prevalent vertebral fractures or a femoral neck BMD T-score of -2.5 or below showed a significant 36% reduction in clinical osteoporotic fractures and a 50% reduction in risk for hip fractures.⁶³

Rapid onset of fracture reduction was demonstrated in the Fosamax International Trial (FOSIT). Patients with a T-score lower than -2.0 had a significant 47% reduction in clinical nonvertebral fractures by 12 months and, in *post-hoc* analysis, a significant reduction in clinical vertebral fractures at 12 months in women with a previous vertebral fracture or femoral neck T-score lower than -2.5.⁶⁴

In a meta-analysis of several alendronate trials, clinical vertebral fractures were reduced at 1 year and hip fractures by 18 months. Treatment with alendronate for 7 years resulted in a continuous increase in bone mass during the 7 years; however, the effect on fractures beyond 3 years could not be assessed because of the lack of a placebo control group beyond that interval.

FLEX (FIT long-term extension trial) enrolled 1099 women treated with alendronate for an average of 5 years into a 5-year placebo-controlled extension. In patients treated for 5 years, BMD in the spine was stable, whereas hip BMD declined for up to 5 years after discontinuation of alendronate. No difference in hip, nonvertebral, or morphometric vertebral fractures was seen in patients taking alendronate for 5 years versus those taking it for 10 years; however, clinical vertebral fractures decreased in those who remained taking alendronate for a total of 10 years.^{65,66}

In men treated for 2 years with 10 mg of alendronate, bone mass increased in both the spine and hip, and a significant reduction in new vertebral fractures was demonstrated.⁶⁷

Risedronate

Risedronate was approved for the prevention and treatment of osteoporosis in the United States in 2000. In the pivotal placebo-controlled clinical trials in postmenopausal women with previous vertebral fractures treated with 5 mg/day for 3 years, incident vertebral fractures were reduced by 41% and 49% and nonvertebral fractures were reduced by 33% ($P = .06$) and 39% ($P = .02$), respectively, in the North American and multinational studies (Vertebral Efficacy with Risedronate Therapy [VERT]-NA and VERT-MN).^{68,69}

In an extension of the VERT-MN trial in which patients (with a placebo control) were monitored for an additional 2 years (5 years total), a 50% reduction in vertebral fractures in years 3 to 5 was demonstrated.⁷⁰ A further 2-year extension without a placebo group showed an 11.5% increase in BMD over the 7-year period.

An RCT with hip fracture as a primary endpoint showed a significant 30% reduction in hip fractures.⁷¹ In those aged 70 to 79 with osteoporosis, a significant 40% reduction was seen, whereas in those older than 80 who were enrolled primarily on the basis of risk factors for falling (not BMD), a nonsignificant 20% reduction in hip fractures was seen. A 1-year observational study in which men were randomized to risedronate or alfacalcidol showed that risedronate reduced new vertebral fractures by 60% relative to alfacalcidol.

Ibandronate

The BONE (Oral Ibandronate Osteoporosis Vertebral Fracture Trial in North America and Europe) trial assessed the effect of 2.5 mg oral ibandronate (and 20 mg every other day for 12 doses every 3 months). After 3 years, new morphometric vertebral fractures were significantly reduced by 62% in the group receiving 2.5 mg/day. Clinical vertebral fractures were also significantly reduced; however, nonvertebral fractures, including hip fractures, were not reduced in comparison to placebo.⁷²

Ibandronate is approved for postmenopausal osteoporosis orally in doses of 2.5 mg/day and 150 mg/mo on the basis of a bridging study in which it was shown that the 150-mg dose increased bone density in the lumbar spine and total hip significantly more than 2.5 mg daily did. The Dosing Intravenous Administration (DIVA) trial compared ibandronate 2 mg given every 2 months, 3 mg every 3 months, and 2.5 mg/day for 1 year. Increases in lumbar spine BMD were significantly greater with the intravenous doses than with the oral dose.⁷³

The doses used in the clinic were either 150 mg orally per month or 3 mg intravenously every 3 months.

Zoledronate

Intravenous zoledronic acid was approved in 2007 for (1) treatment of postmenopausal osteoporosis, (2) treatment and prevention of glucocorticoid-induced osteoporosis in patients expected to be taking glucocorticoids for

at least 12 months, (3) men with osteoporosis to increase bone mass in a once-yearly dosing regimen, and (4) treatment of osteopenia in a biannual dosing regimen.

In the Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly Pivotal Fracture Trial (HORIZON-PFT), women taking zoledronate had a significantly lower rate of new morphometric vertebral fractures (relative risk reduction [RRR], 70%), nonvertebral fractures (RRR, 25%), and hip fractures (RRR, 41%), along with a 6.7% increase in lumbar bone density over a 3-year period.⁷⁴

In the first RCT that examined the post-hip fracture population, the HORIZON Recurrent-Fracture Trial (HORIZON-RFT), patients treated with zoledronic acid once yearly had a significantly reduced risk for new clinical vertebral fracture (RRR, 46%) and any clinical fracture (RRR, 35%). In addition, all-cause mortality was reduced by 28% in this post-hip fracture population.⁷⁵

No impairment in fracture healing occurred when zoledronic acid was administered within 90 days of hip fracture. A *post-hoc* analysis divided treatment timing into 2-week intervals (calculated from surgical repair to the first infusion); patients who received the infusion in the first 2 weeks did not show a significant reduction in fractures or mortality. Combined results of the HORIZON-PFT and HORIZON-RFT showed that zoledronic acid reduced the risk for all clinical fractures by 12 months (HR, 0.75), with reductions at years 2 and 3 being greater than those at year 1.^{76,77}

It is unclear whether dosing at less frequent intervals would be as efficacious as once-yearly dosing. The HORIZON-PFT extension trial randomized women who received 3 yearly doses of zoledronic acid to receive either 3 additional yearly doses or 3 years of placebo. Femoral neck BMD declined only 1.04% after 3 years with placebo, whereas biochemical markers of bone turnover rose only slightly but were still substantially lower than before treatment. The incidence of morphometric vertebral fractures was lower in women treated with 6 years versus 3 years of zoledronic acid. No significant differences were seen in nonvertebral, clinical vertebral, hip, or all clinical fractures. The study suggests that some patients may discontinue treatment after 3 years for up to 3 years; however, since patients did have an increase in morphometric fractures, those at highest risk for future vertebral fractures may benefit from continued therapy.⁷⁸

Almost 20% of subjects who received intravenous zoledronate experienced an acute-phase reaction characterized by low-grade fever, myalgia, headache, arthralgia, bone pain, and nausea, with symptoms generally resolving within 3 days of dosing but possibly lasting up to 7 to 14 days. An acute-phase reaction is more likely to occur in patients who have not previously been exposed to bisphosphonates and is less likely to recur with subsequent dosing.⁷⁹

Zoledronic acid should be considered in patients who are not candidates for oral bisphosphonates, such as those with esophageal strictures or swallowing dysfunction, those who are unable to remain upright, or those in whom oral bisphosphonate therapy has failed. Vitamin D should be replenished before the zoledronate infusion, and patients should be monitored for hypocalcemia. Both serum creatinine and calcium should be measured before each infusion; use of the drug is contraindicated in patients with a creatinine clearance lower than 35 mL/min.

Denosumab

A critical breakthrough in the understanding of bone remodeling came with unraveling of the essential pathways and critical interactions occurring at the cellular level. Receptor activator for nuclear factor- κ B ligand (RANKL), a member of the tumor necrosis factor (TNF) family, is an important mediator of bone remodeling and is expressed by a number of cell types, including osteoblasts, synovial fibroblasts, and activated T cells. RANKL binds to RANK, a receptor on osteoclast membranes, and induces differentiation, activation, and survival of osteoclasts. A regulator of the RANK-RANKL interaction is the soluble cytokine osteoprotegerin (OPG). OPG is a naturally occurring member of the TNF receptor family that functions as a decoy receptor by competing for binding to RANK (Fig. 201.4). Failure of RANKL to bind to RANK results in apoptosis of osteoclast precursors. Murine models with genetic alterations in their RANKL gene or OPG-deficient mice have severe osteoporosis, which can be prevented or reversed by administration of OPG. Excessive OPG can result in an osteopetrotic phenotype.

Denosumab, a fully human monoclonal IgG2 antibody that binds selectively and with high affinity to RANKL and mimics the effect of OPG on RANKL, was approved for use in the United States in 2010. The pivotal phase 3 trial randomized postmenopausal women with osteoporosis to receive subcutaneous denosumab 60 mg every 6 months or placebo.⁸⁰

Subjects treated with denosumab demonstrated a significant 68% reduction in spine fractures, 40% reduction in hip fractures, and 20% reduction

Fig. 201.4 Denosumab is a fully human monoclonal antibody that binds with high affinity to and inhibits the activity of human RANKL, a key mediator of osteoclast activity. RANKL is an essential mediator of the formation, activation, and survival of osteoclasts. OC, osteoclast; OPG, osteoprotegerin; RANK, receptor activator of nuclear factor- κ B; RANKL, RANK ligand.

in nonvertebral fractures. The pharmacodynamics of denosumab differs from that of the bisphosphonates; bone turnover markers decline rapidly, as soon as 12 hours, after an injection and exhibit more rapid recovery after discontinuation. The drug does not accumulate in bone, in contrast to the bisphosphonates. Several of the trials of denosumab reported numeric increases in infections and malignancies. Bone biopsy data revealed an absence of tetracycline labeling in 30% of tested subjects (www.fda.gov).

Side effects of antiresorptive agents

Shortly after the release of alendronate, numerous reports of severe gastrointestinal (GI) side effects were published, primarily esophageal erosions and stricture. RCTs, however, suggest little or no increase in risk for upper GI tract problems if oral bisphosphonates are administered properly. Patients with esophageal motility disorders are at greater risk for toxicity. Rechallenge placebo-controlled studies with both alendronate and risendronate have shown no difference in the occurrence of GI symptoms. With the highest level of evidence, generic alendronate became available in the United States in 2008. A study that compared gains in bone density at 1 year with branded versus generic alendronate showed that gains in lumbar spine BMD were 40% to 50% less, GI adverse events were greater, and persistence was lower with generic than with branded alendronate.

Administration of intravenous bisphosphonates is associated with an influenza-like illness characterized by fever, myalgia, arthralgia, and nausea for 24 to 48 hours after the infusion. Rapid infusion of zoledronic acid has been reported to cause renal failure. Some patients may suffer severe bone pain with bisphosphonates that may be related to the small decrease in serum calcium and subsequent rise in PTH values. Osteonecrosis of the jaw (ONJ) with bisphosphonates was first reported in 2003, initially in cancer patients treated with high doses of intravenous bisphosphonates. No definition of ONJ is universally accepted, but it usually appears as an area of exposed alveolar bone in the mandible or maxilla that does not heal within 8 weeks. A systematic review in 2006 revealed 368 reported cases of ONJ (many cases are not reported); 94% occurred with intravenous bisphosphonates, usually in patients with multiple myeloma or metastatic cancer.⁸¹

About 65% were in the mandible, a third were painless, 60% occurred after a tooth extraction or other surgery, and the rest developed spontaneously. Although the incidence of ONJ with oral bisphosphonates is much less, by mid-2006, approximately 30 cases had been reported in patients receiving oral bisphosphonates. The American Society for Bone and Mineral Research (ASBMR) task force identified 57 cases of ONJ in patients treated with bisphosphonates for osteoporosis and 7 cases in patients who had Paget disease. Risk for ONJ in patients without cancer is estimated to be less than 1 in 100,000.⁸²

A Canadian consensus practice guideline for patients treated for osteoporosis did not recommend dental examination before therapy in those who maintained good oral hygiene, stopped smoking, and had limited alcohol intake.⁸³

No published data support the recommendation that bisphosphonate therapy be discontinued once ONJ develops, but most patients are likely to stop therapy for at least several months.⁸⁴

"Atypical" subtrochanteric fractures of the femur have been associated with long-term bisphosphonate use.^{85,86} Review of radiographs is required since these fractures have a characteristic appearance in that they are transverse or short oblique with a thickened cortex and have a periosteal elevation or beak on the lateral cortex. The ASBMR task force has published a report on this topic.⁸⁷

Parathyroid hormone

Anabolic therapy with teriparatide (recombinant human PTH [rhPTH] 1-34) has been available in the United States since 2002 and is also available in the European Union, as is the full-length rhPTH 1-84. Subjects in the pivotal trial with the full 84-amino acid rhPTH molecule had a higher than expected incidence of hypercalcemia, and the trial program was discontinued in the United States.

Teriparatide was evaluated in an RCT of postmenopausal women with at least one moderate or two mild previous vertebral fractures and a T-score in the hip or spine lower than -1.0 .⁸⁸ Subjects were randomized to 20 or 40 μg daily of rhPTH 1-34 or placebo. Treatment averaged 19 months in the three groups. When compared with placebo, BMD significantly increased by 9.7% and 13.7% in the lumbar spine and by 2.8% and 5.1% in the femoral neck in the 20- and 40- μg groups. The incidence of vertebral fractures was reduced by 65%, and the risk for two or more fractures was decreased by 77% with the 20- μg dose. The incidence of moderate and severe vertebral fractures was reduced by 90%.⁸⁹ Women in the 20- μg treatment group were 35% (all nonvertebral) and 53% (traumatic nonvertebral) less likely to have one or more new nonvertebral fractures. Reanalysis of the original radiographs via quantitative morphometric methodology showed an 84% reduction in vertebral fractures and a 94% reduction in multiple fractures.⁹⁰

In an 11-month RCT in men with osteoporosis, patients were randomized to placebo or treatment with 20 or 40 $\mu\text{g}/\text{day}$ of rhPTH 1-34; the relative risk for new vertebral fractures was 0.5 for the combined 20- and 40- μg PTH-treated group.⁹¹

Teriparatide is indicated for postmenopausal women and men at high risk for fracture. Although the indications give general guidelines for patient selection, they leave the physician with a large amount of discretion and many questions about which patients are most appropriate. Patients with one or more of the following characteristics are appropriate for teriparatide therapy:

- Those who have a significant decline in BMD during antiresorptive therapy
- Those who are unable to take antiresorptive agents because of side effects
- Those who sustain a fracture during antiresorptive therapy
- Patients who are treatment naive and at high risk for fracture

Few data directly comparing bisphosphonates with teriparatide in women with postmenopausal osteoporosis are available; none of the studies report fracture outcomes. McClung and colleagues⁹² compared the BMD response to teriparatide 20 μg and alendronate 10 mg daily. At 18 months, areal BMD increased 10.3% in the teriparatide group and 5.5% in the alendronate group. Volumetric density (quantitative computed tomography [QCT]) increased 19% in the teriparatide group and 3.8% in the alendronate group. Finite element analysis of QCT scans of the L3 vertebral body showed a significantly greater increase in compressive strength at 18 months in patients treated with teriparatide (21.1% vs. 3.7%).⁹³

The effect of simultaneous use of PTH 1-84 and alendronate was examined in the PaTH trial.^{94,95} BMD in the spine increased 6.3% in the PTH group, 6.1% in the combination group, and 4.6% in the alendronate group. Volumetric density (QCT) increased 25.5% in the PTH group, 10.5% in the alendronate group, and 12.9% in the combination group. The authors concluded that there is no evidence of synergy between PTH and alendronate and that concurrent use of alendronate may reduce the anabolic effect of PTH. No data are available on the most important outcome, fracture reduction.

Teriparatide (rhPTH 1-34) plus raloxifene versus teriparatide alone has been evaluated and showed that raloxifene did not inhibit the anabolic effect of teriparatide on the basis of bone density or markers of bone turnover.⁹⁶

Several trials have examined the use of sequential PTH followed by alendronate. In the PaTH trial, PTH for 1 year followed by alendronate for 1 year increased volumetric BMD by 31% (QCT) as compared with 14% in PTH-placebo patients. Treatment with an antiresorptive agent is required to maintain the gains in bone mass with PTH.

The effect of previous treatment with an antiresorptive agent on response to PTH was evaluated by Ettinger and colleagues⁴⁰ in an open-label, non-randomized study comparing the effects of teriparatide following 18 to 36 months of therapy with either raloxifene or alendronate in postmenopausal women with a T-score of -2.0 or lower. After 18 months, patients previously treated with raloxifene had a greater increase in lumbar spine BMD in response to teriparatide than did patients previously treated with alendronate (10.2% vs. 4.1%, respectively). These findings suggest that blunting of the anabolic effect of teriparatide may occur not only with concomitant therapy as illustrated in the PaTH trial but also with sequential therapy in which teriparatide is administered after alendronate. It did not appear that raloxifene blunted the BMD response to teriparatide. No data on fracture reduction are available from this study.

The OPTAMISE study examined the effect of previous risedronate or alendronate on response to PTH and showed that previous alendronate therapy blunted both the bone density and bone marker response to PTH significantly more than previous risedronate therapy did.⁹⁷ After 12 months of therapy with teriparatide, subjects who previously received risedronate showed a 76% significantly greater increase in the density of trabecular bone at the spine as measured by QCT than did those who previously received alendronate (24% vs. 13.7%).

A prospective randomized, double-blind, placebo-controlled trial compared the BMD response to teriparatide in postmenopausal women with osteoporosis who previously received a bisphosphonate versus those who were bisphosphonate naive. After 24 months of treatment with teriparatide, lumbar spine BMD increased significantly more in the treatment-naive group than it did in inadequate responders to bisphosphonate. Although previous bisphosphonate therapy blunts the response to PTH, treatment with teriparatide for 24 months was associated with robust and statistically significant increases in BMD regardless of previous bisphosphonate therapy.⁹⁸

PTH results in periosteal bone formation and a change in bone size. This geometric effect increases strength by increasing diameter and is likely to explain a portion of the effect of PTH on reduction of fractures. The earlier rise in markers of bone formation than in markers of resorption with PTH treatment provides a rationale for the observed increases in bone density. Formation markers peak at 1 month, whereas resorption markers peak at 6 months, thus indicating early osteoblast stimulation and bone formation with a delayed effect on osteoclasts and bone resorption.

Side effects

In the pivotal phase 3 fracture prevention trial using rhPTH 1-34, the only significant side effects were dizziness and leg cramps. Mild hypercalcemia was common (11%), but treatment was discontinued only rarely. Uric acid levels increased 13% to 25% during treatment with rhPTH 1-34, but no gout attacks occurred. Uric acid levels returned to baseline at the end of treatment. The planned 36-month pivotal rhPTH 1-34 trial was terminated early because of the development of osteosarcoma in rat studies.⁹⁹

Osteosarcoma has been reported in one patient treated with PTH (not greater than the expected background incidence of osteosarcoma). Teriparatide should not be prescribed to populations at higher risk for osteosarcoma, including patients with Paget disease of bone, patients with previous radiation therapy involving the skeleton or with implants that deliver radiation, and pediatric populations (and young adults) with open epiphyses. Elevations of alkaline phosphatase should be evaluated before using teriparatide because of the possibility of Paget disease and bone tumors. Patients who have bone metastases or a history of skeletal malignancies should not be treated with teriparatide. Patients with hypercalcemia should be evaluated, and those with hyperparathyroidism and bone metastases should not receive teriparatide. It would also be prudent to check serum calcium levels after starting teriparatide but avoid measurement in the first 16 hours after a dose. The approved lifetime duration of therapy with teriparatide is 24 months.

Strontium ranelate

Strontium occurs naturally as a nonradioactive element and was first isolated in 1808. Strontium competes with calcium for intestinal absorption and, once absorbed, for incorporation into bone and dental tissues. At low doses, strontium ranelate results in uncoupling of bone turnover by stimulating osteoblastic activity and decreasing osteoclastic activity. This would appear to make it different from other antiresorptive agents by increasing formation and reducing resorption of bone. Human and animal studies of strontium ranelate demonstrate it to be an effective therapy for the treatment of osteoporosis.

Two large multicenter, randomized, placebo-controlled trials of postmenopausal osteoporotic women treated with oral strontium ranelate at a

dose of 2 g daily have been published: the Spinal Osteoporosis Therapeutic Intervention (SOTI) trial and the Treatment of Peripheral Osteoporosis (TROPOS) study.^{100,101}

Both showed that strontium ranelate significantly increased bone formation and decreased bone resorption, increased BMD, and significantly reduced the risk for vertebral fractures by between 39% and 45% after 3 years. In TROPOS, patients treated with strontium had a small but significant 16% reduction in non-spine-related fractures. A *post-hoc* analysis demonstrated a significant 36% reduction in the risk for hip fracture in those considered to be at high risk: age older than 74 years and femoral neck T-score of -3 or lower. A preplanned *post-hoc* analysis that pooled data from SOTI and TROPOS showed significant reductions in vertebral, nonvertebral, and symptomatic fractures in women 80 to 100 years old.¹⁰² Strontium has also been shown to reduce the risk for vertebral fractures in postmenopausal women with osteopenia in the spine.¹⁰³

As a result, strontium ranelate (Protelos) received approval for use in more than 90 countries as of 2009 at a dose of one 2-g sachet to be taken before bedtime at least 2 hours after eating along with an 8-oz glass of water; however, it is not approved in either the United States or Canada. In SOTI the most frequent adverse events were nausea and diarrhea, most common in the first 3 months of therapy. A few cases of hypersensitivity syndrome with rash, fever, eosinophilia, and hepatic and renal impairment have been reported.

Summary

The use of antiresorptive therapy has proven benefits in reducing recurrent vertebral fractures by about 40% to 50% when added to a background of calcium and vitamin D supplementation; it does not eliminate the risk for new vertebral fractures, however. Hormone therapy and the nitrogen-containing bisphosphonates alendronate, risedronate, and zoledronic acid, as well as denosumab, have been shown to reduce the risk for nonvertebral fractures, including hip fractures. PTH has been shown to reduce both vertebral and nonvertebral fractures. Such evidence of antifracture efficacy for non-spine-related sites is not available for raloxifene, calcitonin, or ibandronate. The most appropriate patients for PTH treatment are likely to be those with previous fractures, those with very low BMD, and those who lose bone mass and suffer fractures while being treated with antiresorptive therapy. It appears that sequential use of PTH followed by a bisphosphonate will result in a larger increase in BMD than with either agent alone, but whether the increase in bone mass will translate into great reduction of fractures is not known.

The duration of treatment may depend on the initial bone mass, prevalent and incident fractures, other factors that contribute to fracture risk, and the drug used for treatment. The optimal duration of therapy with bisphosphonates is an area currently being debated. Bisphosphonates have a long skeletal half-life and an antiresorptive effect that may persist for years after drug discontinuation. This is not the case with raloxifene and estrogen because their skeletal half-life is short and bone loss would be likely to occur immediately after discontinuation. The off time for denosumab is rapid, and markers of bone resorption will increase to levels higher than pretreatment values 9 to 12 months after the last dose. The implications of discontinuation of denosumab are very different from those for discontinuation of a bisphosphonate.

MANAGEMENT OF VERTEBRAL FRACTURES

The acute pain after a vertebral fracture usually resolves in 4 to 6 weeks. Standard measures of pain relief are used, including analgesics, muscle relaxants, calcitonin, short periods of bed rest, and physical therapy. Spinal orthotics are three-point hyperextension contact braces (sternum, pubic symphysis, lumbar spine; e.g., Jewett and Cash orthoses) and may be helpful. Postural training support devices are designed to decrease kyphosis, move the center of gravity backward, and encourage use of the extensor muscles of the back. No long-term controlled studies of these devices have been conducted.

Operative management

Two percutaneous treatment options for painful vertebral compression fractures, vertebroplasty and kyphoplasty, involve the injection of polymethylmethacrylate (PMMA) into a compressed vertebral body. Studies show that the procedures may restore vertebral height, especially if performed within 6 to 12 weeks of the fracture, and that treated vertebral bodies have increased stiffness and load-bearing capacity, all mechanical advantages that could relieve pain and reduce the risk for additional fracture. Kyphoplasty uses a balloon tamp to create a cavity into which the PMMA is injected. When compared with vertebroplasty, which does not use a balloon, kyphoplasty allows greater filling of the vertebral body and greater height restoration with lower risk for extravasation of PMMA (the balloon creates a cortical shell that impedes extravasation, and the PMMA is injected under lower pressure). The mechanism of pain relief is not known, but reduction in the micromotion of fractured vertebral bodies after the procedure has been hypothesized.

Complications include extravasation of PMMA (up to 30% with vertebroplasty and 10% with kyphoplasty), which can result in neurologic sequelae and embolization to the vertebral venous plexus and to distant sites. Some but not all studies have shown an increased rate of adjacent fractures, and one suggested an increased incidence of subsequent fractures in patients with steroid-induced osteoporosis but not in those with primary osteoporosis. Although kyphoplasty appears to be most effective if performed soon after fracture, a nonrandomized trial in patients with painful vertebral fractures longer than 12 months in duration showed increased vertebral height, reduced pain, and improved mobility when compared with medical management alone.¹⁰⁴

A randomized controlled trial at 21 sites in 8 countries in which 300 patients were randomized to receive kyphoplasty or nonsurgical care documented a mean 36-item Short-Form Health Survey (SF-36) physical component score that improved by 7.2 points in the kyphoplasty group at 1 month with only a 2.0 point improvement in the nonsurgical group. The frequency of adverse events did not differ between groups.¹⁰⁵

A prospective, comparative, randomized trial comparing vertebroplasty and kyphoplasty showed little difference between the two procedures and recommended vertebroplasty on the basis of the higher cost of kyphoplasty.¹⁰⁶

Two recently published high-quality trials compared vertebroplasty with sham procedures and found no beneficial effect on pain and pain-related disability at any time points up to 3 to 6 months.^{107,108}

Glucocorticoid-induced osteoporosis

■ ARTHUR N. LAU ■ PHILIP N. SAMBROOK ■ JONATHAN D. ADACHI

- Glucocorticoids are effective agents for a number of inflammatory conditions, but prolonged use can cause rapid bone loss, particularly in trabecular-rich sites such as the spine and ribs.
- Bisphosphonates and teriparatide are efficacious in treating and preventing glucocorticoid-induced bone loss.
- A significant care gap exists in the screening, prevention, and treatment of glucocorticoid-induced osteoporosis.

INTRODUCTION

Oral glucocorticoids are commonly prescribed for a variety of medical conditions, particularly in the field of rheumatology. They are very useful in controlling inflammation in the short term and serve as an important immunosuppressive agent. However, despite many clinical benefits, their use is associated with significant morbidity and mortality. One of the most significant adverse effects is glucocorticoid-induced osteoporosis (GIOP) and resultant fractures. The association between glucocorticoid excess and osteoporosis has been recognized for more than 80 years. Glucocorticoid therapy is the most common cause of secondary osteoporosis.¹

PATHOPHYSIOLOGY OF GLUCOCORTICOID-INDUCED BONE LOSS

Glucocorticoids affect bone metabolism through a variety of mechanisms (Fig. 202.1). GIOP affects mainly areas rich in cancellous bone, particularly the lumbar spine and proximal end of the femur. Both bone formation and bone resorption processes are affected, and it is the combination of these processes that leads to a significant decline in bone mineral density (BMD) and increased risk of fractures. Bone loss in GIOP occurs in a biphasic pattern. An early transient phase of increased bone resorption occurs in the first year of glucocorticoid use, with a large rapid decline in BMD (6% to 12%) ensuing within the first 12 months, but with long-term therapy, the rate of decline in BMD slows significantly (3% per year) after the rapid resorption phase.²

The reduction in bone formation is probably the most important process in GIOP that contributes to the large reduction in BMD. Glucocorticoids have a direct effect on the osteoblast lineage that leads to decreased new bone formation. Apoptosis of osteoblasts and osteocytes is crucial in the pathophysiology of GIOP.¹ Even low doses of glucocorticoids are sufficient to significantly suppress markers of osteoblast activity, including the propeptide of type 1 N-terminal procollagen (P1NP) and the propeptide of type 1 C-terminal procollagen (P1CP).³ With glucocorticoid use, the caspase-3 pathway is activated, which in turn promotes apoptosis of both osteoblasts and osteocytes. The reduction in number of osteoblasts and osteocytes has been confirmed in histomorphometric studies of patients with GIOP.^{4,5} Osteocyte apoptosis has been associated with a decrease in vascular endothelial growth factor, which in turn reduces skeletal angiogenesis.^{6,7} This disruption of the osteocyte-canalicular circulation contributes to the reduction in biomechanical strength of the affected cancellous bone. This process also plays an important role in the repair of damaged bone.^{6,7} Given the role of the osteocyte-canalicular circulation, disruption of this network may also account for the loss of bone strength, which occurs before a decline in BMD is seen in patients who take glucocorticoids⁸ (Fig. 202.2).

In addition to promoting osteoblast apoptosis, glucocorticoid use also leads to a subsequent decrease in osteoblastogenesis through downregulation of the Wnt signaling pathway. The Wnt signaling pathway is downregulated by Dickkopf-1 (Dkk-1) and sclerostin, both of which are upregulated with glucocorticoid use.^{9,10} Dkk-1 and sclerostin suppress the binding of Wnt to lipoprotein receptor-related proteins-5/6 (LPR-5/6), which in turn limits the ability of β -catenin to be stabilized. Loss of β -catenin from pre-osteoblasts causes a shift in fate of these cells from the osteoblast lineage to the adipocyte lineage, thus leading to a reduction in osteoblastogenesis.¹¹

Peroxisome proliferator-activated receptor- γ 2 (PPAR- γ 2) is also upregulated with long-term glucocorticoid use, which also contributes to a decrease in osteoblastogenesis. When PPAR- γ 2 is upregulated, undifferentiated bone marrow stromal cells are more likely to differentiate into the adipocyte lineage rather than the osteoblast lineage, which accounts for its effect in decreasing osteoblastogenesis. Overall, a combination of an increase in osteoblast apoptosis and a decrease in osteoblastogenesis leads to a decline in new bone formation.

In contrast to its effects on osteoblasts, osteoclastogenesis is promoted and the rate of osteoclast apoptosis is suppressed with glucocorticoid use. This effect is probably due to increased expression of receptor activator of nuclear factor κ B ligand (RANKL) and macrophage colony-stimulating factor by osteoblastic cells.^{1,12} Osteoprotegerin (OPG) is also downregulated, which increases osteoclastogenesis and reduces rates of osteoclast apoptosis.¹³

Aside from its effects on the osteoblast and osteoclast lineages, glucocorticoids also exert indirect effects on bone metabolism. Glucocorticoids reduce intestinal calcium absorption and increase renal calcium clearance.¹ Glucocorticoid use also reduces sex steroid production, which has an influence on bone formation.¹

Risk for fracture is higher in elderly patients with glucocorticoid use. The activity of the 11 β -hydroxysteroid dehydrogenase (11 β -HSD) system may play an important role in this observation. Two isoenzymes, 11 β -HSD1 and 11 β -HSD2, catalyze the conversion between hormonally active and inactive forms of glucocorticoids.¹⁴ The 11 β -HSD1 enzyme serves as an activator, whereas the 11 β -HSD2 enzyme serves as an inactivator. With aging comes an increase in 11 β -HSD1 activity and thus more conversion of glucocorticoids to a hormonally active form.¹⁵

EPIDEMIOLOGY

Glucocorticoids are widely prescribed in medical practice. It is estimated that 2.5% of the elderly population (70 to 79 years of age) are prescribed oral glucocorticoid therapy at any given time.¹⁶ Of these patients, about 22% are prescribed a dose higher than 7.5 mg/day for long-term (>6 months' duration) use.¹⁶ Epidemiologic data from Iceland revealed that osteoporosis developed in an estimated 26% of patients treated long-term with oral glucocorticoids (>6 months' duration).¹⁷

With increasing daily doses, risk of fracture also increases.¹⁸ This was assessed with data derived from the U.K. General Practice Research Database, a large retrospective cohort study that included 244,235 oral corticosteroid users and 244,235 controls. This study revealed that in patients taking higher doses of oral glucocorticoids (at least 7.5 mg of prednisolone or equivalent), the relative risk (RR) for development of a clinical vertebral fracture was 2.83 (95% CI, 2.35 to 2.40), the RR for development of a hip fracture was 2.21 (95% CI, 1.85 to 2.64), and the RR for development of a nonvertebral fracture was 1.44 (95% CI, 1.34 to 1.54).¹⁹ Even a low daily dose of oral glucocorticoids (2.5 to 7.5 mg/day of prednisolone or equivalent) has been shown to increase the risk for vertebral fractures (RR, 1.54; 95% CI, 1.29 to 1.84) and nonvertebral fractures (RR, 1.18; 95% CI, 1.11

to 1.26) (Fig. 202.3).¹⁹ With discontinuation of glucocorticoid therapy, fracture risk declines. However, it is unclear whether the risk returns back to baseline values. A case-control study demonstrated that longer than 1 year of discontinuation of oral glucocorticoids is required before fracture risk returns to levels in the background population.²⁰

Furthermore, patients receiving intermittent high-dose oral glucocorticoids (≥ 15 mg/day and cumulative exposure of ≤ 1 g) have a small increase in fracture rates but no effect on hip fractures. However, in patients receiving doses of 30 mg/day or higher with a cumulative dose of 5 g or greater, the RR for an osteoporotic fracture was 3.63 (95% CI, 2.54 to 5.20), the RR for a hip fracture was 3.13 (95% CI, 1.49 to 6.59), and the RR for a vertebral fracture was 14.42 (95% CI, 8.29 to 25.08).²¹

Fig. 202.1 Glucocorticoids lead to a subsequent decrease in bone quantity and quality and an overall increased risk for fractures. BMD, bone mineral density; M-CSF, macrophage colony-stimulating factor; OPG, osteoprotegerin; PPAR- γ , peroxisome proliferator-activated receptor- γ ; RANKL, receptor activator of nuclear factor κ B ligand. (Adapted from Compston J. Management of glucocorticoid-induced osteoporosis. *Nat Rev Rheumatol* 2010;6:82-8.)

High doses of inhaled glucocorticoids have also been associated with a decline in BMD.²² There are reports of increased fracture rates (hip and vertebral) in both adults and children treated with inhaled glucocorticoids. However, similar fracture rates were seen in those treated with inhaled nonsteroidal bronchodilators, which suggests that the increase in fracture risk may be due to the underlying respiratory disease rather than the inhaled glucocorticoid treatment.^{23,24}

INVESTIGATIONS

Bone mineral density

Bone strength depends on both the quantity and quality of the bone. The most commonly used quantitative imaging measure in osteoporosis is BMD measured by dual-energy x-ray absorptiometry (DEXA). The effects of glucocorticoids on BMD can be measured accurately with DEXA of the lumbar spine, hip, and distal end of the forearm. In GIO, the earliest changes in BMD are often seen at the lumbar spine because of its high content of trabecular bone. A rapid decline in BMD usually occurs within the first 3 months of glucocorticoid use. This rapid decline peaks at about 6 months and is followed by a period of slower, but steady decline with continued use.²⁵

Fig. 202.3 Relative risk for different types of fractures in patients with long-term glucocorticoid use. (Adapted from Van Staa TP, Leufkens HG, Abenhaim L, et al. Use of oral corticosteroids and risk of fractures. *J Bone Miner Res* 2000;15:993-1000.)

Fig. 202.2 A trabecular basic multicellular unit is depicted in the top panel. Selected transverse sections are depicted in the lower panels. Successive stages of quiescence, activation, resorption, formation, and quiescence are depicted. Glucocorticoids may enhance activation early but later delay the interval between completion of resorption and onset of formation. Histomorphometric studies reveal an increase in resorptive surfaces, which is due to decreased recruitment of osteoclast precursors and an increase in osteoblast apoptosis. LC, lining cell; OB, osteoblast; OC, osteoclast; SC, stem cell.

However, the decline in BMD does not completely account for the increase in fracture risk.²⁶ This indicates that glucocorticoids have an effect on not only the quantity of bone but also on the quality of bone produced.

Advanced imaging

Fractures in patients treated with oral glucocorticoids occur at a higher BMD than in those not treated with glucocorticoids.²⁷ Advanced imaging techniques that provide insight into the quality of the bone produced are available. These techniques can provide information regarding the effect of glucocorticoids on the microstructural and macrostructural features of the underlying bone.

The macrostructure of bone can be assessed quantitatively with volumetric quantitative computed tomography (QCT) and high-resolution computed tomography. Low BMD as measured by volumetric QCT of the lumbar spine, total hip, and all hip subregions was significantly associated with prevalent vertebral fractures in postmenopausal women treated long-term with glucocorticoids.²⁸ One study suggested that BMD of the lumbar spine measured by QCT, but not by DEXA, was an independent predictor of vertebral fractures in postmenopausal women receiving glucocorticoids.²⁹

The microstructure of bone can be assessed with micro-magnetic resonance imaging and high-resolution magnetic resonance imaging (hrMRI). An hrMRI study showed changes in trabecular bone in patients receiving glucocorticoids in the setting of organ transplantation. This study showed an increase in fracture rate (vertebral and peripheral) in patients with structural changes seen on hrMRI.³⁰

Biochemical markers

Profound changes in biochemical markers of bone turnover occur in the setting of glucocorticoid treatment. Like other markers of bone formation, serum osteocalcin levels fall within even a few hours of glucocorticoid treatment. With long-term glucocorticoid use, serum osteocalcin levels fall to as low as 30% of their pretreatment levels.

MANAGEMENT

Risk stratification

Glucocorticoid use is an important risk factor for fractures. The decision to intervene with an anti-osteoporotic agent should be based on the patient's absolute fracture risk. FRAX is a fracture risk assessment tool developed by the World Health Organization. It can be used to calculate the 10-year probability of fracture by using a number of clinical risk factors, with or without BMD testing.³¹ Given its importance, glucocorticoid therapy is one of the risk factors included in the FRAX algorithm. FRAX can provide an estimated 10-year fracture risk in patients receiving a daily dose of 2.5 to 7.5 mg of prednisolone (or equivalent). For patients receiving higher doses of glucocorticoids (>7.5 mg/day), the 10-year fracture risk can be adjusted upward to account for the dose-related risk.³²

Current recommendations

Given the high risk for fractures in this population, there is a large emphasis on initiating anti-osteoporotic therapy in patients being treated long-term with oral glucocorticoids. The American College of Rheumatology (ACR), in its latest recommendations (2010), suggested risk stratification of patients taking oral glucocorticoids based on FRAX. The ACR recommended that patients at low to medium risk for fracture (<10% and 10% to 20% probability of a major osteoporotic fracture, respectively) start anti-osteoporotic therapy if the daily dose of oral glucocorticoid equals or exceeds 7.5 mg/day of prednisolone (or equivalent). For high-risk patients (>20% probability of a major osteoporotic fracture), the ACR recommended initiation of anti-osteoporotic therapy for anyone treated with glucocorticoids for longer than 1 month (at any dose) or for anyone treated with daily oral glucocorticoids at a dose of 5 mg/day or higher of prednisolone (or equivalent), even if the duration is less than 1 month.

Similar to the ACR, the International Osteoporosis Federation (IOF) and the European Calcified Tissue Society (ECTS) published a joint guideline for the management of GIOP.³³ The IOF-ECTS developed an algorithm to risk-stratify and treat patients older than 50 years who had been taking oral glucocorticoids for at least a 3-month duration. The committee recommended FRAX assessment in women and men 50 to 70 years of age who were exposed to oral glucocorticoids for a 3-month or longer duration but

with a daily dose of less than 7.5 mg/day (of prednisolone or equivalent). In patients considered to be at high risk for fracture (previous fracture, age >70 years, or daily doses ≥ 7.5 mg/day of prednisolone or equivalent for more than 3 months' duration), the IOF-ECTS recommended initiation of anti-osteoporotic therapy.³³

Calcium and vitamin D

Physiologically, glucocorticoid use exerts an effect on calcium metabolism by decreasing calcium absorption through the gastrointestinal tract. Several trials have assessed the use of calcium supplementation as primary prevention in patients treated with low-dose oral glucocorticoids. However, despite primary prevention with calcium supplementation, there was still a significant decline in BMD,³⁴ which suggests that calcium supplementation alone is insufficient to prevent a decline in BMD in the setting of glucocorticoid use.

The combination of vitamin D with calcium supplementation has been evaluated in a number of trials in the GIOP population. This combination was assessed in both the primary and secondary prevention settings. An early study evaluated the combination of calcium 500 mg/day and vitamin D 50,000 U/wk in patients treated long-term with glucocorticoid therapy. This trial showed a significant increase in BMD, but only BMD of the radius was assessed in this study.³⁵

The combination of calcium and vitamin D was assessed in the primary prevention setting by Adachi and colleagues. Only patients starting high-dose oral glucocorticoid therapy were included. Patients taking oral glucocorticoids were randomized to 1000 mg of elemental calcium per day and 50,000 units of vitamin D per week versus placebo over a 3-year follow-up duration. BMD of the lumbar spine was evaluated. No difference was found in lumbar spine BMD between the calcium/vitamin D combination and the placebo groups over the follow-up period.³⁶

A secondary prevention trial assessed the combination of calcium and vitamin D supplementation in patients treated long-term with glucocorticoids. Patients were randomized to receive calcium (1000 mg/day) and vitamin D₃ (500 U/day) versus placebo. This trial reported a 2.0% annual decline in lumbar spine BMD in the placebo group versus a 0.7% increase with the calcium/vitamin D combination.³⁷

Supplementation with active vitamin D metabolites has been assessed in a number of trials. The two most commonly used forms of activated vitamin D are calcitriol (1,25-dihydroxyvitamin D) and alfacalcidol (1 α -hydroxyvitamin D). One study evaluated the effect of calcium, calcitriol, or calcitonin in 103 patients starting therapy with oral glucocorticoids.³⁸ At the 12-month follow-up, a statistically significant decline in lumbar spine BMD was noted in the calcium-treated group (4.3% decline over a 12-month period) when compared with the calcitriol group (1.3% decline) and the calcitonin group (0.2% decline). Another randomized controlled trial compared alfacalcidol treatment with calcium supplementation alone in 145 patients starting glucocorticoid therapy.³⁹ At the 12-month follow-up period, a 0.4% increase in lumbar spine BMD occurred in the alfacalcidol group versus a 5.7% decline in the calcium group. Furthermore, a meta-analysis showed the beneficial effect of active vitamin D metabolites. When compared with no treatment or with calcium supplementation alone, treatment with active vitamin D metabolites resulted in a greater increase in BMD and a statistically significant reduction in vertebral fractures.⁴⁰ However, a meta-analysis performed by the same group showed that active vitamin D metabolites were not as effective as bisphosphonates in preventing loss of BMD in the lumbar spine (2.1% increase in the alendronate group vs. a 1.9% decline in the alfacalcidol group).⁴¹

Calcitonin

Calcitonin was assessed in both primary and secondary prevention trials. In two primary prevention trials, addition of calcitonin to active vitamin D metabolites (alfacalcidol and cholecalciferol) resulted in no significant improvement in BMD or vertebral fracture rates.^{34,42}

Bisphosphonates

Bisphosphonates act by binding to hydroxyapatite crystals in bone and have an inhibitory effect on osteoclasts. Overall osteoclast activity is inhibited by decreasing osteoclast maturation, increasing osteoclast apoptosis, and decreasing the activity of mature osteoclasts. The decrease in osteoclast numbers and activity results in an overall anti-resorptive effect. The mechanism by which bisphosphonates exert their protective effect in the setting of GIOP is still unclear. A period of rapid bone resorption occurs soon after initiation of glucocorticoid therapy. Inhibition of this process

may account for the early improvement in BMD seen after the initiation of bisphosphonate therapy. It is suggested that bisphosphonates reduce the rate of glucocorticoid-induced apoptosis of osteocytes, which is an important factor in the pathogenesis of GIOP.⁴³

A number of trials have assessed the efficacy of bisphosphonates in the setting of GIOP. These trials evaluated the use of bisphosphonates in both primary and secondary prevention settings. A primary prevention trial randomized 141 patients initiating glucocorticoid therapy to receive cyclic etidronate and calcium supplementation of 500 mg versus placebo. At the 12-month follow-up period, BMD of the lumbar spine and the greater trochanter was significantly increased (increase of $0.6\% \pm 0.54\%$ and $1.46\% \pm 0.67\%$, respectively) in comparison to the control group (decrease of $3.23\% \pm 0.60\%$ and $2.74\% \pm 0.66\%$, respectively).⁴⁴ There were also significantly fewer new vertebral fractures in the etidronate groups than in the placebo group.⁴⁴

Two randomized, placebo-controlled trials assessed the use of alendronate as prophylaxis in patients starting glucocorticoid therapy. The combined results of the two trials included 477 patients randomized to either alendronate or placebo treatment. Patients in the alendronate group received either 5 or 10 mg/day. In addition, patients in both groups received 800 to 1000 mg of elemental calcium and 250 to 500 IU of vitamin D daily. The alendronate group had a mean increase in BMD in the lumbar spine of $2.1\% \pm 0.3\%$ and $2.9\% \pm 0.3\%$, respectively, for the 5- and 10-mg groups. The placebo group had a decrease of $0.4\% \pm 0.3\%$, which was a statistically significant difference ($P < .001$). Similarly, femoral neck BMD increased by $1.2\% \pm 0.4\%$ and $1.0\% \pm 0.4\%$ in the 5- and 10-mg alendronate groups, respectively ($P < .01$) and decreased by $1.2\% \pm 0.4\%$ in the placebo group ($P < .01$).⁴⁵ After completion of the trial, a 12-month extension was performed to evaluate the efficacy of alendronate over a 24-month duration. In 208 patients who continued in the 12-month extension, those randomized to receive alendronate preserved bone mass in the lumbar spine, femoral neck, and greater trochanter, in contrast to the placebo group, in which bone mass was not preserved. Over the 24-month follow-up period, fewer new vertebral fractures occurred in the alendronate groups combined than in the placebo group (0.7% vs. 6.8% , $P = .026$).

Risedronate is another oral bisphosphonate that has been evaluated in the setting of GIOP. In a primary prevention trial, 224 patients newly initiated to long-term glucocorticoid therapy were randomized to receive either risedronate (2.5 or 5 mg) or placebo daily over a 12-month follow-up duration.⁴⁶ Patients in both groups also received 500 mg of elemental calcium daily. The results were similar to those in the two prior primary prevention studies using either etidronate or alendronate. At the 12-month follow-up period, lumbar spine BMD increased by $0.6\% \pm 0.5\%$ in the 5-mg group and decreased by $0.1\% \pm 0.7\%$ in the 2.5-mg risedronate group. In the placebo group, lumbar spine BMD decreased by $2.8\% \pm 0.5\%$. The mean difference in BMD between the 5-mg risedronate and placebo groups was $3.8\% \pm 0.8\%$ ($P < .001$) at the lumbar spine, $4.1\% \pm 1.0\%$ ($P < .001$) at the femoral neck, and $4.6\% \pm 0.8\%$ ($P < .001$) at the greater trochanter. At the 12-month follow-up mark there was also a trend toward a reduction in incident vertebral fractures in patients treated with 5 mg risedronate daily versus placebo (5.7% vs. 17.3% , $P = .072$).⁴⁶ The effects of risedronate were evaluated in patients treated long-term with glucocorticoids (>7.5 mg of prednisone or equivalent). Reid and colleagues randomized 290 men and women treated long-term with glucocorticoids to receive either risedronate (2.5 or 5 mg/day) or placebo daily for a 12-month duration. At the 12-month follow-up mark, a statistically significant difference in BMD was noted between the risedronate and placebo groups at the lumbar spine ($P < .001$), femoral neck ($P = .004$), and trochanter ($P = .01$).⁴⁷ Although it was not powered to show efficacy in preventing fractures, there was a reduction in the incidence of vertebral fractures by 70% in the combined risedronate groups versus placebo ($P = .042$).⁴⁷

In addition to oral bisphosphonates, intermittent intravenous bisphosphonates have also been tested in the setting of GIOP. A randomized, double-blind, double-dummy noninferiority trial was conducted in which 833 patients starting glucocorticoid therapy were randomized to receive either zoledronic acid (5 mg intravenously once yearly) or risedronate (5 mg orally daily).⁴⁸ Patients were stratified into a prevention subgroup (those who received glucocorticoid treatment for less than 3 months) and a treatment subgroup (those who received glucocorticoid treatment for more than 3 months). At 12 months, zoledronic acid was found to be noninferior to risedronate in terms of an increase in lumbar spine BMD in the treatment subgroup (mean difference, 1.36% ; 95% CI, 0.67 to 2.05 ; $P = .0001$). Furthermore, zoledronic acid was superior to risedronate with respect to an increase in lumbar spine BMD in the prevention subgroup (mean difference, 1.96% ; 95% CI, 1.04 to 2.88 ; $P < .0001$).⁴⁸ In this trial the rate of new vertebral fractures was very low (five in the two zoledronic acid subgroups

combined and three in the risedronate group), with no statistically significant difference between the treatments.

A small randomized controlled trial also assessed the role of intermittent intravenous pamidronate in preventing GIOP. A total of 27 patients newly starting long-term glucocorticoid therapy were randomized to receive either pamidronate (induction infusion of 90 mg with subsequent infusion of 30 mg every 3 months) or elemental calcium alone (800 mg/day).⁴⁹ At 12 months the patients randomized to pamidronate showed a significant increase in BMD at the lumbar spine and femoral neck (3.6% and 2.2% increase, respectively), whereas a 5.3% decline in BMD occurred at both the lumbar spine and femoral neck in the calcium-only group.

Currently, the bisphosphonates alendronate, risedronate, etidronate, and zoledronic acid are all approved for patients taking glucocorticoids. They are effective in the setting of both prophylaxis and treatment of GIOP.

Parathyroid hormone

Parathyroid hormone (PTH) plays a critical role in the regulation of calcium metabolism. Intermittent pulsatile administration of PTH produces an overall anabolic effect on bone turnover. The intermittent pulse of PTH binds to the PTH-1 receptor, a G protein-coupled protein. This binding subsequently activates the cyclic adenosine monophosphate-dependent protein kinase A and protein kinase C signaling pathways, which in turn promote osteoblastogenesis and osteoblast activity.⁵⁰ Teriparatide is a recombinant human PTH (1-34) that has been shown to be effective for the treatment of osteoporosis in postmenopausal women and men. The Fracture Prevention Trial demonstrated that in postmenopausal women, teriparatide treatment resulted in a significant increase in BMD at the level of the lumbar spine, femoral neck, and total body. The trial also demonstrated a reduction in risk for both vertebral and nonvertebral fractures.⁵¹

Given that a decrease in osteoblastogenesis and an increase in osteoblast apoptosis play a critical role in the pathogenesis of GIOP, an anabolic agent such as teriparatide would be a physiologically rational agent for the treatment and prevention of GIOP. Human PTH 1-34 was first assessed in the setting of GIOP by Lane and colleagues.⁵² Fifty-one postmenopausal women with osteoporosis who were concurrently taking glucocorticoids were randomized to receive teriparatide plus estrogen versus estrogen only. At the 12-month follow-up, lumbar spine BMD increased by 11% as measured by DEXA versus no change in the estrogen-only group ($P < 0.001$). In addition, lumbar spine BMD increased by 35% as measured by QCT versus a 1.7% increase in the estrogen-only group ($P < 0.001$).⁵² At the 24-month follow-up (after the study was extended for an additional 12 months), lumbar spine BMD measured by DEXA increased by 12.6% ($P < .001$), and lumbar spine BMD measured by QCT increased by 45.9% ($P < .001$). However, no significant improvement in BMD of the femoral neck or total hip was seen.⁵³

Furthermore, the efficacy of teriparatide in the setting of GIOP was also assessed in a randomized controlled trial that included both men and women who were taking oral glucocorticoids (≥ 5 mg of prednisone or equivalent) for at least 3 months at the time of enrollment. A total of 214 patients were randomized to receive 20- μ g injections of teriparatide daily versus 10 mg of alendronate daily.⁵⁴ At the 36-month follow-up, a significant increase in BMD of the lumbar spine (measured by DEXA) occurred in the teriparatide group versus the alendronate group (increase of 11.0% vs. 5.3% , respectively; $P < 0.001$). A significant increase also occurred in femoral neck BMD (increase of 6.3% vs. 3.4% , respectively; $P < .001$) and total hip BMD (increase of 5.2% vs. 2.7% , respectively; $P < .001$) in the teriparatide group versus the alendronate group. In addition, fewer subjects sustained vertebral fractures in the teriparatide group than in the alendronate group (1.7% vs. 7.7% , respectively; $P = .007$), with most of the fractures occurring in the first 18 months.⁵⁵ No significant difference was seen between the groups in the incidence of nonvertebral fractures at the 36-month follow-up.

RANKL inhibition: denosumab

RANKL plays a critical role in the activation, differentiation, and life span of osteoclasts. Denosumab is a fully human monoclonal IgG2 antibody against RANKL. Denosumab has been shown to be effective in the treatment of osteoporosis in postmenopausal women and in men.^{56,57}

Glucocorticoid use is associated with overexpression of RANKL and suppression of OPG, which is an endogenous inhibitor of RANKL.⁵⁸ Given the underlying pathophysiology, denosumab would be an agent with biologic plausibility to be tested for the treatment and prevention of GIOP. Currently, few trials have assessed the efficacy of denosumab in this setting. One study evaluated the use of denosumab in patients with rheumatoid arthritis treated with oral glucocorticoids and methotrexate. This phase 2,

double-blind controlled trial randomized patients to receive either placebo, 60-mg injections of denosumab every 6 months, or 180-mg injections of denosumab every 6 months. The study was initially designed to evaluate the effect of denosumab on structural damage from the underlying rheumatoid arthritis.⁵⁹ However, BMD (measured by DEXA) of the lumbar spine and total hip was assessed as a secondary outcome. At the 6- and 12-month follow-up marks, a statistically significant increase in BMD of the lumbar spine and total hip occurred in the denosumab-treated groups. There was also a reduction in serum bone turnover markers (type I C-telopeptide and serum PINP) from baseline in the denosumab groups.⁶⁰

CARE GAP IN THE SCREENING, PREVENTION, AND TREATMENT OF GLUCOCORTICOID-INDUCED OSTEOPOROSIS

Despite the known deleterious effects of glucocorticoids on bone and the availability of agents effective in preventing and treating GIOP, a significant care gap still exists. A retrospective chart review from an academic rheumatology practice revealed that in rheumatoid arthritis patients treated with glucocorticoids, only 25% received calcium or vitamin D (or both) and only 42% received an anti-osteoporotic agent.⁶¹ In addition, only 23% of patients had a baseline BMD measurement. Male patients and premenopausal women were less likely to be screened with a baseline BMD.

In another study conducted in an academic Veterans Administration medical center, a retrospective chart review was conducted to identify

clinicians who prescribed long-term glucocorticoids. The clinicians included primary care providers, subspecialists, and medical trainees. These identified clinicians were invited to attend a focus group and complete a questionnaire. Common barriers in the management of GIOP identified through this process included a lack of knowledge, having limited time during the clinic visit, patient nonadherence, and system problems.⁶² Potential system problems identified through provider focus group questionnaires include difficulty obtaining a DEXA scan and difficulty obtaining appropriate treatment of GIOP.

CONCLUSION

Despite the effectiveness of glucocorticoids in treating a variety of inflammatory conditions, GIOP is a significant and common adverse effect. A FRAX assessment or similar algorithm should be performed on all patients starting glucocorticoid therapy to risk-stratify those at moderate and high risk for fractures. All patients starting oral glucocorticoid therapy should be prescribed calcium and vitamin D supplementation; calcium supplementation alone is ineffective in preventing glucocorticoid-induced bone loss. Oral bisphosphonates are an effective first-line therapy for both prevention and treatment of GIOP. Intravenous zoledronic acid and subcutaneous teriparatide are both options, especially if oral bisphosphonates are contraindicated or not tolerated. Despite numerous effective therapies, there is still a significant care gap in the prevention and treatment of GIOP. Clinician and patient education is essential to ensure that GIOP is not underrecognized and undertreated.

Osteomalacia and rickets

■ MICHAEL F. HOLICK

- Osteomalacia is caused by a defect in the mineralization of osteoid laid down by mature osteoblasts. Once osteoid is laid down, adequate calcium-phosphorus product in the circulation results in normal mineralization, with deposition of calcium hydroxyapatite forming mineralized bone.
- The most common causes of osteomalacia/rickets are vitamin D deficiency and calcium deficiency. Any acquired or inherited disorder that alters absorption of phosphorus in the intestine and enhances excretion of phosphorus via the kidneys will also cause osteomalacia and rickets.
- Osteomalacia cannot be distinguished from osteopenia or osteoporosis by either radiographic examination or determination of bone mineral density. Physicians should be alert for the presence of osteomalacia in adults because it is often seen in men and women with osteopenia and osteoporosis.
- Treatment of vitamin D deficiency and correction of calcium and phosphorus intake result in complete resolution of osteomalacia/rickets when caused by these nutritional deficiencies.
- Several hereditary and acquired disorders affect both calcium and phosphorus metabolism and lead to rickets and osteomalacia. Management of these disorders depends on the cause and should be based on treating the mechanism resulting in osteomalacia/rickets or removing the offending agent that may be precipitating the mineralization defect.

INTRODUCTION

Osteomalacia by definition means that osteoblasts have laid down a collagen matrix, but there is a defect in its ability to be mineralized. In children, a defect in mineralization of osteoid in long bones and failure or delay of mineralization of endochondral new bone formation at the growth plate leads to the classic skeletal deformities of rickets. However, in adults the disorder takes on a different character as a result of failure of mineralization of newly formed osteoid at sites of bone turnover in regions of periosteal or endosteal apposition. Several causes of poor or absent skeletal mineralization can lead to both rickets and osteomalacia and are reviewed in this chapter.

CALCIUM, PHOSPHORUS, AND VITAMIN D METABOLISM

The major skeletal mineral components are calcium and phosphate. Thus any alteration in the calcium-phosphate product in the circulation can result in a mineralization defect in the skeleton. Vitamin D plays a critical role in maintaining both serum calcium and phosphate concentrations.¹ Vitamin D (D represents D₂ or D₃) is obtained by exposure of the skin to sunlight or through dietary sources^{2,3} (Fig. 203.1).

Vitamin D is converted in the liver by vitamin D-25-hydroxylase (25-OHase) to form the major circulating form of vitamin D, 25-hydroxyvitamin D (25[OH]D).^{1,2} 25(OH)D is, however, biologically inert and requires hydroxylation in the kidneys on carbon 1 by 25-hydroxyvitamin D-1 α -hydroxylase (1-OHase) to form 1 α ,25-dihydroxyvitamin D (1,25[OH]₂D), the biologically active form of vitamin D responsible for regulating calcium and phosphorus homeostasis.^{1,2} Interaction of 1,25(OH)₂D with its vitamin D nuclear receptor (VDR) in the small intestine results in an increase in the

efficiency of intestinal calcium absorption.^{1,2,4} 1,25(OH)₂D also stimulates phosphate absorption. It is the calcium $\times$ phosphate product in the circulation and in the extravascular space that plays a major role in normal mineralization of the osteoid laid down by osteoblasts.

EFFECT OF VITAMIN D ON BONE METABOLISM

It is known that vitamin D is not necessary for mineralization of the osteoid matrix.^{5,6} Patients with vitamin D-resistant rickets have a mutation in their VDR and severe rickets and osteomalacia. When these patients were infused with calcium and phosphorus to maintain a normal calcium-phosphate product, the unmineralized osteoid was mineralized.⁶

Interaction of 1,25(OH)₂D with its VDR in osteoblasts increases the expression of alkaline phosphatase, osteocalcin, and receptor activator of nuclear factor κ B ligand (RANKL).⁷ The alkaline phosphatase produced by osteoblasts is important in bone mineralization because patients with a decrease in bone-specific alkaline phosphatase, known as hypophosphatasia, suffer from a mineralization defect in osteoid.^{8,9} Osteocalcin is the major noncollagenous protein in the skeleton. Although its function is not well understood, it appears to have a role in osteoclastic activity.¹⁰

RANKL, once expressed on the surface of an osteoblast, interacts with its receptor RANK on osteoclast precursors. This intimate interaction leads to signal transduction that results in the formation of multinucleated mature osteoclasts (Fig. 203.2).^{1,7,10} These osteoclasts, under the direction of a variety of cytokines,¹⁰ increase resorption of bone by releasing hydrochloric acid to dissolve the mineral and collagenases to dissolve the matrix (Fig. 203.3).

CAUSES OF OSTEOMALACIA/RICKETS

Consequences of vitamin D deficiency on bone mineralization

When a child or adult is deficient in vitamin D, the efficiency of intestinal calcium absorption is decreased and a transient reduction in serum ionized calcium takes place. Recognition of the reduction in serum ionized calcium by the calcium sensor in the parathyroid glands results in an increase in the secretion of parathyroid hormone (PTH).^{1,2,11} PTH conserves calcium by increasing tubular reabsorption of calcium throughout the renal tubule^{12,13} and stimulates the production of 1,25(OH)₂D.^{2,13} and both PTH and 1,25(OH)₂D increase the expression of RANKL on osteoblasts, which in turn mobilizes osteoclast precursors to become mature osteoclasts so that calcium and phosphorus can be removed from the skeleton by resorption of bone.^{1,2,12,13} (see Fig. 203.2). Thus, unless there are no longer any calcium deposits in the skeleton, the blood level of calcium is usually normal or low normal in both vitamin D-deficient children and adults.^{1,2,14}

PTH also causes internalization of the sodium-dependent phosphate cotransporter (NaPi-2A), which results in loss of phosphate into urine.^{1,2,12,13} This ultimately causes the blood phosphorus level to be lowered to a degree that the calcium-phosphate product is no longer adequate to mineralize the osteoid matrix (see Fig. 203.3c).

Thus the major cause of osteomalacia is secondary hyperparathyroidism and the low normal or low serum phosphate level. The fasting biochemistry for rickets and osteomalacia is summarized in Table 203.1.^{8,14}

Definition of vitamin D deficiency and insufficiency

The concentration of 25(OH)D that needs to be achieved to maximize bone health is still being debated. The Institute of Medicine (IOM) and the Endocrine Society defined vitamin D deficiency as a serum level of 25(OH)D

Fig. 203.1 Synthesis and metabolism of vitamin D for regulating calcium, phosphorus, and bone metabolism. During exposure to sunlight, 7-dehydrocholesterol (7-DHC) in the skin is converted to pre-vitamin D₃ (pre-D₃). Pre-D₃ is immediately converted by a heat-dependent process to vitamin D₃. Excessive exposure to sunlight degrades pre-D₃ and vitamin D₃ to inactive photoproducts. Vitamin D₂ and vitamin D₃ from dietary sources are incorporated into chylomicrons, which are transported by the lymphatic system into the venous circulation. Vitamin D (D represents D₂ or D₃) made in the skin or ingested in the diet can be stored in fat cells and then released from them. Vitamin D in the circulation is bound to the vitamin D-binding protein, which transports it to the liver, where vitamin D is converted by vitamin D-25-hydroxylase (25-OHase) to 25-hydroxyvitamin D (25(OH)D). This is the major circulating form of vitamin D that is used by clinicians to measure vitamin D status (although most reference laboratories report the normal range to be 20 to 100 ng/mL, the preferred healthful range is 30 to 60 ng/mL). 25(OH)D is biologically inactive and must be converted in the kidneys by 25-hydroxyvitamin D-1 α -hydroxylase (1-OHase) to its biologically active form 1,25-dihydroxyvitamin D (1,25(OH)₂D). Serum phosphorus, calcium, fibroblast growth factor 23 (FGF-23), and other factors can either increase (+) or decrease (–) the renal production of 1,25(OH)₂D. 1,25(OH)₂D feedback regulates its own synthesis and decreases the synthesis and secretion of parathyroid hormone (PTH) in the parathyroid glands. 1,25(OH)₂D increases expression of 25-hydroxyvitamin D-24-hydroxylase (24-OHase) to catabolize 1,25(OH)₂D and 25(OH)D to the water-soluble biologically inactive calcitroic acid, which is excreted in bile. 1,25(OH)₂D enhances intestinal calcium absorption in the small intestine by stimulating expression of the epithelial calcium channel (ECaC, also known as transient receptor potential cation channel subfamily V member 6 [TRPV6]) and calbindin 9K (calcium-binding protein [CaBP]). 1,25(OH)₂D is recognized by its receptor in osteoblasts, which causes an increase in expression of receptor activator of nuclear factor κ B ligand (RANKL). Its receptor RANK on the preosteoclast binds RANKL, which induces the preosteoclast to become a mature osteoclast. The mature osteoclast removes calcium and phosphorus from bone to maintain blood calcium and phosphorus levels. Adequate calcium and phosphorus levels promote mineralization of the skeleton and maintain neuromuscular function. OJ, orange juice; UVB, ultraviolet B. (Courtesy M.F. Holick, PhD, MD, © 2007.)

Fig. 203.2 Both 1,25-dihydroxyvitamin D (1,25(OH)₂D) and parathyroid hormone (PTH) stimulate the mobilization of calcium from the skeleton by interacting with their respective receptors on osteoblasts, which induces the expression of receptor activator of nuclear factor κ B (RANK) ligand (RANKL). RANK on the immature osteoclast's plasma membrane binds to RANKL, which causes it to mature and coalesce with other osteoclast precursors to become mature multinuclear osteoclasts. Osteoprotegerin (OPG) is a soluble decoy of RANK that binds to RANKL and inhibits osteoclastogenesis. (Courtesy M.F. Holick, PhD, MD, © 2007.)

lower than 20 ng/mL.^{15,16} Several studies have demonstrated, however, that PTH levels plateau when serum 25(OH)D is between 30 and 40 ng/mL.^{17,18} Furthermore, in a study of 675 otherwise healthy German adults who died prematurely in accidents and had bone biopsies performed and their blood collected, 26.5% of these otherwise healthy adults had evidence of osteomalacia and 36.1% had evidence of osteoidosis (buried osteoid within mineralized bone).¹⁹ The Endocrine Society noted that 21% of adults with serum levels of 25(OH)D between 21 and 29 ng/mL had evidence of osteomalacia.^{19,20} Based on this and other evidence, it was concluded that vitamin D insufficiency should be defined as a 25(OH)D level of 21 to 29 ng/mL and vitamin D sufficiency as a 25(OH)D level of 30 ng/mL or higher.¹⁶ Both the IOM and the Endocrine Society recommended that a 25(OH)D blood level of up to 100 ng/mL is safe.

Calcium deficiency

In Africa, where children are exposed to sunlight daily, rickets develops as a result of calcium deficiency.¹⁵ A diet poor in calcium will result in an increase in PTH levels, which causes hyperphosphaturia. Thus, in children living in Africa, India, and Bangladesh who ingest approximately 200 mg of calcium daily and have a diet high in phytates and oxalates, which irreversibly bind calcium in the gut and prevent its absorption, rickets and osteomalacia will develop.^{21–29}

Phosphate deficiency, heritable and acquired disorders

Nutritional phosphate deficiency is uncommon because our diet is rich in phosphate. Human breast milk, cow's milk, and infant formulas have enough phosphate to satisfy an infant's requirement. There are, however, several

Fig. 203.3 Bone histology demonstrating (a) increased osteoclastic bone resorption (arrows) as a result of secondary hyperparathyroidism, (b) normal mineralized trabecular bone, and (c) osteomalacia with widened unmineralized osteoid matrix (lighter areas). (Courtesy M.F. Holick, PhD, MD, © 2007.)

acquired and inherited disorders that cause phosphate wasting into urine and can lead to severe hypophosphatemia and subsequent rickets and osteomalacia.

X-linked hypophosphatemic rickets and autosomal dominant phosphatic rickets are caused by either an increase in the production of fibroblast growth factor 23 (FGF-23) and other phosphatonins or a decrease in their catabolism and therefore severe phosphate wasting into urine. FGF-23, produced by osteocytes, causes internalization of the NaPi cotransporter and phosphaturia.¹⁴ In addition, the elevated blood level of FGF-23/phosphatonins inhibits the renal production of 1,25(OH)₂D, thus diminishing the efficiency of both intestinal calcium and phosphate absorption.^{14,30-33}

Oncogenic osteomalacia is due to the production of FGF-23/phosphatonins by benign or malignant tumors.³⁴ The result is severe hypophosphatemia

secondary to increased phosphate wasting into urine. Because this disease is often seen in adults, the clinical skeletal manifestations of the osteomalacia include aches and pains in the bones and muscles and signs of periosteal discomfort induced by applying pressure on the periosteum of the sternum, radius, ulna, and anterior aspect of the tibia. A radiograph of the skeleton may show osteopenia, and bone densitometry often reveals osteoporosis.^{8,35}

Fanconi syndrome and renal tubular acidosis

Fanconi syndrome is a disorder of the renal proximal tubules that results in decreased reabsorption of phosphorus, glucose, and amino acids, accompanied by metabolic acidosis secondary to proximal tubular bicarbonate wasting (type II renal tubular acidosis).^{36,37} Typically, these patients have hypophosphatemia, hyperphosphaturia, and a low tubular maximum inorganic phosphate concentration. Serum calcium is usually normal, alkaline phosphatase is elevated, PTH and 25(OH)D are normal, but serum 1,25(OH)₂D is inappropriately low or low normal.^{29,36-38} Children with Fanconi syndrome have classic radiographic evidence of rickets, whereas adults exhibit changes consistent with osteomalacia.³⁹

As noted in Box 203.1, a multitude of acquired and heritable disorders can cause Fanconi syndrome.³⁶ Patients found to have hypophosphatemia on a fasting blood specimen should be evaluated for Fanconi syndrome and the underlying cause identified and either treated appropriately or the offending agent removed.³⁶

Aluminum

The aluminum antacids used to prevent phosphate absorption in patients with chronic kidney disease can lead to the development of osteomalacia (see Chapter 203).^{15,40} Aluminum is a trivalent cation that at low concentrations stimulates osteoblastic activity but at higher concentrations inhibits the release of PTH and 1-OHase activity. It also inhibits osteoblastic activity and is deposited on the mineralization surface of the skeleton, thereby preventing further mineralization of osteoid. These patients often have little osteoblastic or osteoclastic activity, which results in a very inactive bone-remodeling state known as adynamic bone disease. A bone biopsy specimen that demonstrates stainable aluminum on the mineralization surface helps make the diagnosis of aluminum-induced osteomalacia.^{8,15,40}

Heavy metals

Several heavy metals can cause phosphaturia.^{8,15,41,42} Cadmium exposure causes Itai-Itai disease. High cadmium exposure has wide-ranging pathologic effects on the body, including damage to the glomerulus and renal tubular function. Besides leading to renal failure, it initially causes proteinuria and phosphaturia.¹⁵

Fluoride

Fluoride in low concentrations stimulates osteoblastic activity.¹⁵ However, at high concentrations fluoride becomes incorporated into the skeleton as a calcium fluorhydroxyapatite crystal. Because fluoride has a larger atomic weight than the OH that it replaces, the skeleton appears to be hyperdense on radiography and bone densitometry. Ingestion of food and water with a high fluoride content of between 3 and 16 ppm is associated with increased bone density, which leads to stiffness, rigidity, and limitation of movement at the spine and can also lead to skeletal deformities and fractures.^{8,15,43-45}

In certain populations, including children in India who are exposed to high dietary fluoride and have a low-calcium diet, severe skeletal deformities consistent with rickets develop.^{15,46-48} Histologically, biopsy specimens show widened osteoid seams, poorly mineralized new bone formation, and areas of hypermineralization.¹⁵

Drugs

A variety of drugs can cause rickets and osteomalacia.^{1,8,15} In children and adults who are institutionalized and taking several antiepileptic medications, rickets/osteomalacia often develops.^{1,14,15,49-51} It is now recognized that not only antiseizure medications but also glucocorticoids, certain antiretroviral medications, and even St. John's wort can cause vitamin D deficiency and resultant rickets and osteomalacia. These medications interact with the steroid xenobiotic receptor that binds to the retinoic acid X receptor, which leads to increased catabolism of 25(OH)D.^{1,14,51}

Osteomalacia has developed in patients with Paget disease who were treated with the bisphosphonate etidronate at a dose of 400 mg daily for more than 6 months.^{1,8,15,52} To prevent this complication, patients with Paget

(b) AP views of the forearms demonstrate transverse lucency with sclerotic borders of the right distal radial metadiaphysis and transverse sclerotic changes in the same location on the distal end of the left radius (i.e., Looser zones, arrows). (Modified from Keller K, Barnes P. Rickets versus abuse: a national epidemic. *Pediatr Radiol* 2008;38:1210-6.)

disease took the medication for several months, stopped taking it for several months, and then restarted it again to control the Paget disease but prevent the side effect of osteomalacia.^{8,15}

The newer class of aminobisphosphonates is very effective in treating Paget disease when given either daily, weekly, or monthly, without any evidence of osteomalacia based on bone biopsy specimens (see Chapter 206). These potent bisphosphonates are also used for the prevention and treatment of osteoporosis and do not cause osteomalacia (see Chapter 201).

Ifosfamide, used to treat solid tumors, has been associated with renal Fanconi syndrome and hyperphosphaturia.^{53,54} Saccharated ferric oxide injected intravenously can cause transient proximal renal tubular damage that leads to phosphaturia.⁵⁵ A wide variety of other drugs have been associated with hypophosphatemia, osteomalacia, and rickets^{8,15} (see Box 203.1).

RADIOGRAPHIC AND BIOCHEMICAL MANIFESTATIONS OF OSTEOMALACIA AND RICKETS

It is not possible to distinguish osteomalacia from osteopenia and osteoporosis either by radiographic examination or by bone densitometry. The only exception is if the radiographic examination reveals Looser zones (Fig. 203.4). These zones are radiolucent lines penetrating through the cortex perpendicular to the shaft and are most often seen in the medial cortices of the femurs and in the pelvis and ribs. In children, rickets/osteomalacia is easily detected because the epiphyseal plates have not closed. There is widening of the physis along with fraying, cupping, and splaying of the metaphyses (Fig. 203.5). The diaphyses of the long bones often appear to be less dense (i.e., osteopenic) and show thinning of the cortices with periosteal new bone formation.^{8,15}

In utero, vitamin D deficiency can cause infantile rickets.⁵⁶ A decrease in mineralization of the fetal skeleton can increase the infant's risk for sustaining a variety of skeletal fractures during birth that often go undetected and heal quickly. If solely breastfed, the infant will not receive sufficient vitamin D because human breast milk on average contains just 25 IU of vitamin D per liter unless the mother is ingesting at least 4000 IU of vitamin D daily.⁵⁷ Therefore the infant's skeleton remains fragile, and handling of the infant can lead to nontraumatic fragility fractures of long bones and the rib cage. A radiograph of the long bones or chest may reveal a fracture or radiographic findings that appear to be a fracture but may be a consequence of rickets (see Fig. 203.4). A skeletal survey is often performed and reveals multiple

fractures in various stages of healing. The child may be removed from the parents' care and given to the child protection agency and the parents possibly prosecuted for child abuse. However, more careful analysis of the radiographs deemed to show multiple fractures in various stages of healing can also reveal that these "fractures" have been overinterpreted and misread as fractures caused by trauma (see Fig. 203.4).⁵⁸

Rickets and osteomalacia are associated with a variety of abnormalities in blood biochemistry (Box 203.2).^{1,8,15} However, it is often the initial symptoms or manifestations of osteomalacia that will prompt the diagnosis before any biochemical abnormalities are appreciated. The reason for this is that the abnormal biochemical findings can vary depending on the cause. For example, a child with severe vitamin D deficiency will have low normal or low serum calcium; low normal or low fasting serum phosphorus; elevated alkaline phosphatase, PTH, and 1,25(OH)₂D; and a 25(OH)D level lower than 15 ng/mL. If the child has been deficient in vitamin D for a prolonged period or has very little calcium intake, the biochemical manifestation is often hypocalcemia associated with all of the other biochemical abnormalities. An adult with vitamin D deficiency will have normal or low normal serum calcium, low normal or low serum fasting phosphorus, normal alkaline phosphatase, elevated PTH, normal or elevated 1,25(OH)₂D, and a 25(OH)D level lower than 20 ng/mL. However, if the cause is due to an acquired disorder that results in severe phosphate wasting into urine, these patients will have normal or low normal serum calcium, elevated PTH, low serum phosphorus, elevated alkaline phosphatase, low or low normal 1,25(OH)₂D, and normal 25(OH)D.

CLINICAL FINDINGS

Children with rickets often have skeletal abnormalities, including a rachitic rosary, bowed or knocked knees, frontal bossing, soft fontanelles, and severe muscle weakness (Fig. 203.6). Frequently, children with rickets have other subtle symptoms as noted in Box 203.3.

In adults, osteomalacia is not associated with any overt skeletal signs. However, patients with osteomalacia complain of throbbing, aching bone discomfort. They often note that the bone discomfort is worse when sitting or lying in bed. They also have proximal muscle weakness and aching in their muscles.^{1,8,15,29,50} To make the diagnosis, pressing with the thumb or forefinger with some force on the sternum, radius, ulna, and anterior aspect of the tibia will often result in wincing bone discomfort. Frequently, physicians conclude that discomfort when pressing on the skeleton is consistent

(b) Distal ends of the femurs and proximal ends of the right tibia and fibula from a rachitic child. (c) Radiograph of the wrist of this rachitic child. (Courtesy M.F. Holick, PhD, MD, © 2007.)

BOX 203.2 CLINICAL MANIFESTATIONS OF RICKETS

Restlessness/irritability
Sweating of the head
Skeletal signs in about 6 to 9 months
Head somewhat square
Fontanelles opened/frontal bossing
Osseous borders soft (craniotables)
Teething delayed
Enlargement of costochondral junctions
Muscles flabby
Upper respiratory tract infections
Anemia (Von Jaksch–Luzet syndrome)

with a tender point and the diagnosis of fibromyalgia. In many cases these patients are suffering from periosteal bone discomfort consistent with osteomalacia.⁵⁹

Although the exact cause of the muscle weakness and bone discomfort is not fully understood, it is thought that because the major cause of osteomalacia is vitamin D deficiency and skeletal muscle has VDRs, the lack of $1,25(\text{OH})_2\text{D}$ interacting with skeletal muscle VDRs increases the muscle weakness. Collagen matrix laid down by osteoblasts on a periosteal surface with no mineralization provides little structural support for the periosteal covering, which is heavily innervated with sensory fibers. Thus the deformation caused by pressing on the periosteal covering leads to immediate bone discomfort. In addition, the collagen matrix acts like gelatin dessert and, once hydrated, expands. As a result, application of outward pressure on the periosteal covering leads to the sensation of throbbing, aching bone discomfort.⁵⁹

STRATEGIES FOR THE TREATMENT AND PREVENTION OF OSTEOMALACIA

Vitamin D deficiency is defined as a serum $25(\text{OH})\text{D}$ concentration lower than 20 ng/mL. However, to maximize intestinal calcium absorption and to minimize circulating PTH levels, it is desirable to maintain a $25(\text{OH})\text{D}$ level higher than 30 ng/mL.^{1,16} Most children and adults have a circulating blood $25(\text{OH})\text{D}$ level of between 15 and 25 ng/mL. For every 100 IU of vitamin D_2 or vitamin D_3 ingested, the blood level of $25(\text{OH})\text{D}$ increases by approximately 1 ng/mL.^{60,61} Thus, to achieve a blood $25(\text{OH})\text{D}$ level higher than 30 ng/mL, it has been recommended by the Endocrine Society that neonates during the first year receive 400 IU of vitamin D per day and that children older than 1 year and all adults receive 600 to 1000 IU and 1500 to 2000 IU of vitamin D per day, respectively.¹⁶ For obese children and adults, the

Fig. 203.6 Child with rickets demonstrating the bowed-leg deformity and rachitic rosary. The child is being held up because of severe muscle weakness. (Courtesy M.F. Holick, PhD, MD, © 2007.)

amount of vitamin D ingested should be increased by twofold to threefold.^{1,2,16}

These recommendations differ from the IOM's recommendations in part because of the fact that the IOM based its recommendations on a population model in which it was assumed that children and adults have sufficient vitamin D^{15} (Table 203.2). However, because it is now recognized that vitamin D deficiency is common worldwide,¹⁹ it is reasonable to follow the recommendations of the Endocrine Society, which used a medical model to recommend vitamin D intake for the treatment and prevention of vitamin D deficiency.¹⁶

BOX 203.3 CAUSES OF OSTEOMALACIA/RICKETS

Vitamin D deficiency
 Calcium deficiency
 Hypophosphatemia
 Fanconi syndrome
 Pseudovitamin D deficiency rickets, vitamin D–dependent rickets type 1
 Vitamin D–resistant rickets, vitamin D–dependent rickets type 2
 X-linked hypophosphatemic rickets
 Autosomal dominant hypophosphatemic rickets
 Oncogenic osteomalacia
 Hypophosphatasia
 Malabsorption syndrome
 Hypokalemic distal renal tubular acidosis
 Wilson disease
 Renal failure, chronic
 Cystinosis
 Phenytoin
 Glucocorticoids
 Highly active antiretroviral therapy
 Etidronate
 Glutethimide
 Heavy metals
 Cancer drugs

To treat vitamin D deficiency, 50,000 IU of vitamin D₂, which is the major pharmaceutical form of vitamin D available in the United States, once a week for 12 weeks or twice a week for 6 weeks will often raise the blood level above 30 ng/mL.⁶² Patients who are severely vitamin D deficient with a 25(OH)D level of less than 10 ng/mL, patients who are taking medications that would enhance vitamin D destruction, and obese patients may require an additional 12 weeks of therapy with 50,000 IU of vitamin D₂. Once the blood level of 25(OH)D is higher than 30 ng/mL, vitamin D sufficiency can be maintained by taking 50,000 IU of vitamin D once every 2 weeks.⁶³ An alternative is to treat with a vitamin D supplement, 5000 IU of vitamin D per day for 2 months followed by 2000 IU of vitamin D per day.¹⁶ The American Academy of Pediatrics recommended that all infants and children receive 400 IU of vitamin D per day, which will prevent rickets in children.⁶⁴

Children and adults who have rickets or osteomalacia caused by calcium deficiency should be treated with the adequate intake recommended for calcium, which is 800 mg/day for children younger than 12 years, 1300 mg/day for teenagers, 1000 mg for adults 19 to 50 years of age, and 1200 mg/day for adults older than 50. They should also be taking an adequate amount of vitamin D to maximize the benefit of the calcium.^{15,65}

Patients with phosphate wasting need to take either Neutra-Phos or sodium phosphate in amounts of 250 to 500 mg three to five times per day along with 0.5 to 1.0 mg of 1,25(OH)₂D₃ (calcitriol) twice per day.^{1,15,30} It should be noted that more frequent dosing of phosphate at lower doses to help maintain serum levels of phosphate is desirable for two reasons. The

TABLE 203.2
Vitamin D dietary reference intakes

Life stage group	IOM recommendations				Committee [†] recommendations	
	AI	EAR	RDA	UL	Daily allowance (IU/day)	RUL (IU)
Infants						
0-6 mo	400 IU (10 µg)	—	—	1000 IU (25 µg)	400-1000	2000

first is that maintenance of a more normal calcium phosphate product will help in the mineralization of osteoid. Second, taking large amounts of phosphate orally results in a transient decrease in serum ionized calcium, which

stimulates the parathyroid glands to produce and secrete PTH. Chronic stimulation of the parathyroid glands by transient hypocalcemia can result in tertiary hyperparathyroidism.⁶⁶

Primary hyperparathyroidism: rheumatologic manifestations and bone disease

■ NATALIE E. CUSANO ■ SHONNI J. SILVERBERG ■ JOHN P. BILEZIKIAN

- Primary hyperparathyroidism is diagnosed on the basis of an elevated serum calcium concentration and a parathyroid hormone level that is either elevated or inappropriately normal.
- “Classic” primary hyperparathyroidism was associated with rheumatologic manifestations.
- Primary hyperparathyroidism is now generally an asymptomatic disorder with rheumatologic manifestations seen only rarely and as the subject of case reports.
- The incidence of gout and calcium pyrophosphate crystal deposition or pseudogout was previously found to be increased in patients with primary hyperparathyroidism.
- Pseudogout was also described in the past in patients with primary hyperparathyroidism after successful parathyroid surgery.
- Metabolic conditions such as primary hyperparathyroidism, though uncommon, should be considered in patients with pyrophosphate arthropathy before the age of 65 and can occur, though rarely, in patients older than 65.
- Skeletal involvement in primary hyperparathyroidism is detected with dual energy x-ray absorptiometry, with preferential involvement of cortical sites such as the distal third of the radius.
- Parathyroidectomy is indicated in patients with primary hyperparathyroidism who meet the accepted surgical criteria.
- Cinacalcet is approved by the Food and Drug Administration for the medical treatment of advanced primary hyperparathyroidism.

INTRODUCTION AND HISTORY

The effects of parathyroid hormone (PTH) on its major target organs the skeleton and kidneys gave rise to the original description of primary hyperparathyroidism more than 70 years ago as a disease of “bones, stones and groans.”^{1,2} The classic bone disease, osteitis fibrosa cystica, included degranulation of the skull (or “salt-and-pepper skull”), distal tapering of the clavicles, subperiosteal bone resorption (particularly in the phalanges), brown tumors, and bone cysts. In addition to these skeletal manifestations, rheumatologic manifestations of primary hyperparathyroidism were described commonly.³ Gout⁴ and pseudogout were appreciated as classic manifestations of primary hyperparathyroidism.^{5,6} Gout or pseudogout occasionally developed even after successful parathyroid surgery.^{7,8} Patients also periodically complained of nonspecific arthralgias. A neuromuscular disorder with atrophy of type II muscle fibers was sometimes featured as a major manifestation of the disease.⁹ These aspects of primary hyperparathyroidism were consistent with the traditional idea that PTH in excess can affect organ systems besides the skeleton and kidneys.

Over the past 30 years, however, this classic description of primary hyperparathyroidism has been replaced by one that is primarily asymptomatic. The shift in manifestation from a symptomatic to an asymptomatic clinical phenotype has been due to the widespread use of multichannel autoanalyzers, which typically include serum calcium measurement.^{10,11}

CURRENT PROFILE OF HYPERPARATHYROIDISM

Most patients with primary hyperparathyroidism are women in their postmenopausal years.¹²⁻¹⁴ The serum calcium concentration is typically within 1 mg/dL above the upper limit of normal, and the PTH concentration is usually 1.5 to 2 times the upper limit of normal.^{2,12,14} Hypercalciuria is seen in approximately 40% of patients. Hypophosphatemia, reflecting the physiologic actions of PTH to induce phosphaturia, is seen in less than 25% of patients. Overt hyperparathyroid bone disease with specific radiologic findings is vanishingly rare. The incidence of kidney stones has diminished to approximately 15% to 20% of all patients, although it remains the most common clinical complication of primary hyperparathyroidism.¹⁵ Consistent with this modern manifestation, patients rarely have overt neuromuscular disease but may still complain of vague muscle weakness and easy fatigability. Rheumatologic manifestations that can be ascribed specifically to the articular system and that are reviewed here are uncommon and have been relegated to case reports. These manifestations can be divided into the impact on crystal-related arthropathies (gout and pseudogout) and nonspecific effects on bones and joints.

CRYSTAL ARTHROPATHIES

Gout

The incidence of gout appears to be increased in patients with primary hyperparathyroidism who have hyperuricemia.¹⁶⁻¹⁸ Rather dramatic radiologic manifestations can sometimes be seen, as in the case report of an individual with a lytic lesion that was initially assumed to be a brown tumor but found on joint aspiration to contain urate deposits.¹⁹ A possible explanation for the association of gout and primary hyperparathyroidism is the increased levels of serum uric acid that have been described in some,⁴ but not all¹⁵ cohorts of patients with primary hyperparathyroidism. Data on serum uric acid in primary hyperparathyroidism are limited. However, in one study, 53 subjects with primary hyperparathyroidism had significantly higher serum uric acid levels, along with a reduction in the clearance of uric acid,⁴ than did age- and sex-matched control subjects. Within 6 months after successful parathyroid surgery in 26 subjects, serum uric acid levels declined significantly. It has been suggested that PTH might inhibit uric acid excretion in the proximal renal tubule. Pseudohypoparathyroidism, a disease associated with renal resistance to PTH, was found in one kindred to be associated with hypouricemia and an increase in the fractional excretion of uric acid, thus suggesting an important role of PTH in the renal handling of uric acid.²⁰

Calcium pyrophosphate crystal deposition disease (pseudogout)

Primary hyperparathyroidism and calcium pyrophosphate crystal deposition (CPPD) disease, now named pyrophosphate arthropathy, have been associated in numerous reports.^{5,21-27} As is the case for CPPD in general, aging confers greater risk for radiographic evidence of CPPD in primary hyperparathyroidism. Mechanisms other than chronic hypercalcemia might be particularly relevant to the process of CPPD in the joints of subjects with primary hyperparathyroidism. It has been speculated that the function of proteoglycans that normally inhibit calcium pyrophosphate crystallization²⁸ might be impaired by the elevated calcium in serum and joint fluid.^{24,26} It

has also been postulated more recently that hyperparathyroid patients with CPPD exhibit abnormal local cartilage metabolism of pyrophosphate.²⁹ The nucleoside triphosphate pyrophosphohydrolase enzymes, which normally catalyze the production of pyrophosphate, appear to be overactive.³⁰ Excessive nucleoside triphosphate pyrophosphohydrolase activity could promote the formation and ultimate deposition of calcium- and pyrophosphate-containing material in the joints.³¹

A clinical attack of pseudogout is an uncommon complication of CPPD disease, although this is true for patients both with and without primary hyperparathyroidism. Metabolic conditions such as primary hyperparathyroidism, though an uncommon cause, should be considered in patients in whom CPPD occurs before 65 years of age and can be considered in those older than 65.^{32,33} Interestingly, pseudogout has been described in patients with primary hyperparathyroidism after successful parathyroid surgery when the serum calcium level has returned to normal.^{7,8,21,24,34-37} In one series in which 20 patients with primary hyperparathyroidism and pseudogout were described,³⁸ CPPD had previously been diagnosed in 8, whereas the diagnosis was made in the remainder after parathyroidectomy. In another report, three hyperparathyroid patients with radiographic CPPD received immediate, aggressive vitamin D treatment after parathyroidectomy in an attempt to prevent postoperative pseudogout,³⁹ and indeed, pseudogout did not develop after parathyroidectomy in these patients. However, without a control group, one cannot be certain that the attacks would have occurred if they had not been treated with vitamin D.

The occurrence of pseudogout after parathyroid surgery appears to be triggered by the fall in serum calcium.^{21,24} As the serum calcium concentration falls, it is presumed that the synovial fluid calcium concentration also falls, thus rendering the pyrophosphate crystals more soluble and allowing their release into the synovial space.^{22,40} The idea that a rapid reduction in serum calcium is primarily responsible for an attack of CPPD and not the primary hyperparathyroidism *per se* comes from other reports in which pseudogout has been precipitated after medical treatment that leads to hypocalcemia. One report described a case of pseudogout in the setting of mithramycin treatment of hypercalcemia⁴¹ and another in the setting of hypocalcemia after pamidronate treatment.⁴² Similarly, injection of hyaluronate into the joint space can precipitate pseudogout, possibly because the phosphate in the hyaluronate preparation may lower intraarticular calcium concentrations and lead to crystal shedding.⁴³

PRIMARY HYPERPARATHYROIDISM AND THE SKELETON

There is evidence that excessive PTH may have an adverse effect on joints in addition to the specific situations mentioned earlier. These rheumatologic effects are consistent with the classic notion that PTH is catabolic at skeletal sites. However, our understanding of the skeletal effects of PTH has changed along with the evolving clinical profile of primary hyperparathyroidism. Thus, in the series of Silverberg and colleagues,⁴⁴ less than 2% of patients with primary hyperparathyroidism had specific skeletal manifestations of hyperparathyroidism noted on conventional x-ray examination. Along with the rarity of overt skeletal disease in primary hyperparathyroidism, other less common target organs of the primary hyperparathyroid state, including the articular system, have also become rare manifestations. The effects of mild primary hyperparathyroidism on the skeleton are therefore the key consequence to be considered.

Skeletal effects of mild primary hyperparathyroidism

With primary hyperparathyroidism now commonly manifested as an asymptomatic disorder, it has been possible to address a more subtle but critically important question: do patients with asymptomatic primary hyperparathyroidism have evidence of skeletal involvement? Using dual-energy x-ray absorptiometry (DXA), Silverberg and coworkers⁴⁴ provided evidence that skeletal involvement does occur in patients with asymptomatic primary hyperparathyroidism, although it is site specific. Bone mineral density (BMD) is reduced in the distal third of the radius, a site that contains mainly cortical bone. In the lumbar skeleton, which is enriched in cancellous bone, skeletal mass is relatively well preserved in patients with primary hyperparathyroidism, with only small reductions from age- and sex-specific norms.^{44,45} BMD of the hip region, which contains a more even admixture of cortical and cancellous elements, is intermediate between that of cancellous and cortical sites (Fig. 204.1).

Even though DXA has provided valuable information, high-resolution peripheral quantitative computed tomography (HRpQCT) of the radius and

Fig. 204.1 Bone densitometry in primary hyperparathyroidism. Data are shown in comparison to age- and sex-matched normal subjects. Divergence from expected values is different at each site ($P = .0001$). (Reprinted with permission from Silverberg SJ, Shane E, de la Cruz L, et al. *Skeletal disease in primary hyperparathyroidism*. *J Bone Miner Res* 1989;4:283-91.)

tibia has allowed examination of the skeleton in greater detail.^{46,47} HRpQCT has confirmed that cortical bone is affected at both sites, but it has also demonstrated that cancellous bone may also be affected.

Fracture data in patients with primary hyperparathyroidism are not clear because virtually all information comes from retrospective or cross-sectional studies.⁴⁸⁻⁵⁴ A Mayo Clinic study⁵¹ of more than 400 patients showed an increase in both vertebral and nonvertebral fractures. In a review of several studies, Mosekilde⁵⁴ reported that the incidence of fractures was increased in primary hyperparathyroidism. By classifying patients according to disease severity, Vignali and associates⁵⁵ observed an increased incidence of vertebral fractures in both symptomatic and asymptomatic patients.

Parathyroid hormone therapy and joint manifestations

It is also important to consider the rheumatologic consequences of “medical” hyperparathyroidism as a consequence of therapy with PTH. Teriparatide [recombinant human PTH(1-34)] increases BMD and reduces the incidence of fractures in postmenopausal women with osteoporosis (Fig. 204.2).^{56,57} Teriparatide also increases BMD in men with primary or hypogonadal osteoporosis.⁵⁸ When compared with alendronate, it has a greater effect in reducing vertebral fractures in patients with glucocorticoid-induced osteoporosis.⁵⁹ As opposed to primary hyperparathyroidism, in which exposure to elevated PTH is continuous, once-daily administration of teriparatide stimulates new bone formation on trabecular and cortical surfaces by preferential stimulation of osteoblast activity.⁶⁰ Although it is theoretically possible that adverse rheumatologic effects, formerly seen frequently in primary hyperparathyroidism, could be experienced in some PTH-treated patients, this has not been noted clinically. Clinical trials have shown that treatment with teriparatide results in 3% of patients having serum uric acid concentrations above the upper limit of normal as opposed to 1% of placebo-treated patients. However, the hyperuricemia did not result in an increase in episodes of gout.^{56,58,59} Moreover, gout attacks were not increased in patients with mild or moderate renal impairment whose uric acid concentration increased.⁶¹

Transient increases in the serum calcium concentration have been noted in controlled trials, but articular cartilage calcification has not been reported as an adverse event.^{56,58,59,62-64} The incidence of pseudogout in patients treated with teriparatide is not increased over that in patients treated with placebo. Much less information is available about PTH(1-84), the full-length recombinant human PTH molecule, in part because of the fact that it is not approved in the United States. The experience in Europe, where it is approved in many countries for the treatment of postmenopausal osteoporosis, does not suggest that the data reviewed earlier with regard to rheumatologic manifestations are any different from that of teriparatide.^{65,66}

Fig. 204.2 Reduction in the risk for new morphometric vertebral fractures in postmenopausal women with severe osteoporosis after PTH(1-34) [Forteo] 20 mcg/day over a median treatment period of 19 months versus placebo. ARR, absolute risk reduction; RR, relative risk. (Data from Neer RM, Arnaud CD, Zanchetta JR, et al. Effect of parathyroid hormone [1-34] on fractures and bone mineral density in postmenopausal women with osteoporosis. *N Engl J Med* 2001;344:1434-41.)

DIAGNOSIS AND TREATMENT OF PRIMARY HYPERPARATHYROIDISM

Diagnosis of primary hyperparathyroidism is based on an elevated serum calcium concentration and a PTH level that is either elevated or inappropriately normal. When the PTH level is elevated in a patient with hypercalcemia, the differential diagnosis includes the use of thiazide diuretics or lithium, familial hypocalciuric hypercalcemia, and tertiary hyperparathyroidism associated with end-stage renal disease. Malignancy-associated hypercalcemia should not be a consideration when the PTH level is high because the hypercalcemic agent in this condition, PTH-related protein, is not detected by the currently available immunoradiometric assays for PTH.

Surgical treatment

Surgery is indicated for patients with overt symptoms of classic disease (i.e., kidney stones, osteitis fibrosa cystica). In patients with few if any symptoms, guidelines to aid in clinical decision-making are based on the Third International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism (Table 204.1).⁶⁷⁻⁷² Patients who successfully undergo parathyroidectomy show rapid normalization of serum calcium and PTH levels. Improvement in BMD at the spine and hip follows over a 3- to 4-year period after surgery.¹⁵ Most patients who are asymptomatic and do not meet the surgical criteria do well without evidence of progressive disease. However, approximately a third of patients will experience progressive disease.¹⁴ Only age appears to be predictive of progression: patients younger than 50 years are significantly more likely than those older than 50 to experience worsening disease.⁷³

Medical treatment

Development of a medical approach to asymptomatic primary hyperparathyroidism has been of considerable interest. The calcimimetic agent

TABLE 204.1

Criteria for parathyroid surgery in patients with asymptomatic primary hyperparathyroidism

Variable	Surgical criteria*
Serum calcium	1.0 mg/dL (0.25 mmol/L) greater than the upper limit of normal
Creatinine clearance	Reduced to <60 mL/min (calculated)
Bone mineral density	T-score less than -2.5 at any site [†] and/or previous fragility fracture
Age	<50 yr

*Surgery is also indicated for patients in whom medical surveillance is neither desired nor possible.

[†]Lumbar spine, total hip, femoral neck, or distal third of the radius.

From Bilezikian JP, Khan AA, Potts JT Jr; Third International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism. Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the third international workshop. *J Clin Endocrinol Metab* 2009;94:335-9.

cinacalcet (Sensipar) is the only medical therapy approved for primary hyperparathyroidism in the United States. It is indicated for individuals with advanced disease. Cinacalcet is a calcimimetic that binds to a region of the calcium receptor that increases its affinity for calcium. The subsequent increase in intracellular calcium in parathyroid cells leads to a reduction in the synthesis and secretion of PTH. Cinacalcet has been shown to normalize serum calcium levels for more than 5 years in patients with primary hyperparathyroidism.⁷⁴⁻⁷⁶ PTH levels fall modestly but not usually into the normal range. Bone density does not increase with cinacalcet. Gout and pseudogout have not been reported with this treatment.

Estrogen therapy in postmenopausal women with primary hyperparathyroidism is associated with small reductions in the serum calcium concentration and increases in bone density, along with stable PTH levels.⁷⁷ Raloxifene, a selective estrogen receptor modulator, is a potential alternative that has shown calcium-lowering effects similar to estrogen in a small pilot study of postmenopausal women with primary hyperparathyroidism.⁷⁸ Bisphosphonates have also been considered as a possible medical approach to primary hyperparathyroidism. Alendronate has been shown to increase lumbar spine BMD in patients with primary hyperparathyroidism by approximately 4% to 6%.⁷⁹⁻⁸¹ In most studies, serum calcium and PTH levels do not change significantly.

CONCLUSION

In the past, symptomatic primary hyperparathyroidism was associated with abnormalities in the articular system. Now that primary hyperparathyroidism is generally asymptomatic in the United States and in most of the developed world, rheumatologic manifestations are mainly of historic interest. Primary metabolic conditions such as primary hyperparathyroidism, though uncommon, should be considered in patients with CPPD occurring before the age of 55 years and can be considered in those older than 55. In patients with rheumatologic manifestations along with primary hyperparathyroidism, a search for other conditions should be undertaken before concluding that they might be unusually affected in this manner by the hyperparathyroid state.

Renal osteodystrophy

■ PAUL D. MILLER

- Renal osteodystrophy is a heterogeneous group of metabolic bone disorders that accompany chronic kidney disease (CKD). The derangements in mineral metabolism begin even in early CKD (stages 1 to 3: glomerular filtration rate [GFR] between 90 and 30 mL/min).
- A specific diagnosis of the type of renal bone disease is made most objectively by double tetracycline-labeled quantitative bone histomorphometry (biopsy).
- All forms of renal osteodystrophy may feature low bone mineral density (BMD) or fragility fractures. The World Health Organization criteria, well accepted for the diagnosis of osteoporosis in postmenopausal women and elderly men, cannot be used to diagnose osteoporosis in individuals with CKD (stage 4-5/5D: GFR <30 mL/min or 15 mL/min with or without dialysis [D]) but can be used to make the diagnosis in early (stages 1 to 3) CKD.
- The diagnosis of osteoporosis in patients with stage 4-5/5D CKD is made by excluding other forms of renal osteodystrophy in the setting of low BMD or fragility fractures.
- Specific approaches are used to treat specific forms of renal osteodystrophy (e.g., hyperparathyroidism, aluminum bone disease, chronic metabolic acidosis).
- Based on *post-hoc* analysis, oral bisphosphonates in doses approved by the U.S. Food and Drug Administration for the treatment of postmenopausal, glucocorticoid-induced, or male osteoporosis seem to be safe in patients with stage 4 CKD, at least for a 2- to 3-year period of use. No data are available on the efficacy or safety of bisphosphonates for stage 5/5D CKD. Intravenous bisphosphonates are safe in the usual doses for stages 1 to 3 CKD; slowing the infusion time to 30 to 60 minutes seems to be safe for off-label use of zoledronic acid in stage 4-5/5D CKD. Intravenous ibandronate does not appear to require a slower rate of injection in stage 4-5/5D CKD. Denosumab has no GFR registration restrictions because it is not cleared by the kidney.
- More data are needed to define the relationship between low BMD and fracture risk in the various heterogeneous forms of renal osteodystrophy and whether bisphosphonates or denosumab can reduce fracture risk in osteoporotic patients with severe stage 5/5D CKD or in those with severe secondary hyperparathyroidism.
- Bisphosphonates are contraindicated in patients with osteomalacia and adynamic renal bone disease. In adynamic bone disease there remains the possibility that reducing bone turnover by any antiresorptive pharmacologic agent may be associated with an increase in the risk for vascular calcification.

INTRODUCTION

Renal osteodystrophy is the term used to define the heterogeneous group of metabolic bone disorders that accompany a declining glomerular filtration rate (GFR) (Box 205.1).^{1,2} Although one of these forms of renal bone disease may be present in patients with different stages of chronic kidney disease (CKD), patients may also move from one form to another, either as a process of the natural biology of renal bone disease or as a result of the treatments used to manage a specific form of renal bone disease. Recently, the Kidney Disease Improving Global Outcome (KDIGO) working group has defined the bone diseases that accompany CKD as systemic diseases in that they are associated with vascular calcification and abnormalities in bone turnover, a

condition termed chronic kidney disease–mineral and bone disorder (CKD-MBD).³ Even though no distinct methods are available to make a diagnosis of CKD-MBD, the abnormalities in bone turnover that universally accompany CKD are often associated with vascular calcification. The presence of elevated levels of parathyroid hormone (PTH) or serum phosphorus may suggest the presence of CKD-MBD in patients with CKD. The Disease Outcome Quality Initiative (KDOQI) of the National Kidney Foundation (NKF) has classified the degrees of CKD according to the GFR in patients with known intrinsic renal disease (Table 205.1).⁴ The NKF divided the broad category of stage 3 CKD (GFR, 30 to 60 mL/min) into two categories—stage 3A (45 to 60 mL/min) and 3B (30 to 45 mL/min)—and added quantitative levels of proteinuria to the classification because recent data have linked the level of proteinuria to the prognosis for progression of CKD. Proteinuria (>300 mg/g creatinine or >500 mg/24 hr) serves as a cut point that adds a risk factor for progression of CKD over and above a low GFR *per se*.⁵ In addition, aging is associated with a reduction in GFR even without any known intrinsic renal disease. The Third U.S. National Health and Nutrition Examination Survey reported that 25% of otherwise healthy adults have GFR levels lower than 25 mL/min.⁶ It is not known whether bone metabolism differs in patients whose GFR is reduced because of intrinsic parenchymal damage as opposed to age-related reductions in GFR without another specific intrinsic renal diagnosis.

At each level of CKD a specific form of renal osteodystrophy may be detected by quantitative bone histomorphometry. The earliest form of renal bone disease (secondary hyperparathyroidism) may be defined by quantitative histomorphometry or biochemical profiling (elevated 1-84 intact PTH) as early as stage 3 CKD (GFR, 30 to 60 mL/min). Even though there is an exponential relationship between the declining level of GFR and the height of endogenous PTH, elevated PTH levels (secondary hyperparathyroidism) may also be seen in patients with various forms of osteoporosis from other causes that may not be related to a reduced GFR (e.g., low 25-hydroxyvitamin D levels, calcium malabsorption, hypercalciuria). Only after correcting other reversible factors that may also lead to secondary hyperparathyroidism can the elevated serum PTH level be attributed to the reduction in renal function.

The KDOQI guidelines (based on both opinion and evidence) provide suggestions concerning the management of secondary hyperparathyroidism when attributable to intrinsic renal damage.⁴ In addition, suggestions have been published for the management of patients with postmenopausal, male, and glucocorticoid-induced osteoporosis who have secondary hyperparathyroidism not related to a reduction in renal function.⁷⁻¹⁵

The other forms of renal bone disease (osteomalacia, mixed renal osteodystrophy, adynamic renal bone disease, and aluminum bone disease) are less common until stage 5 CKD (end-stage renal disease [ESRD] with a GFR lower than 15 mL/min or undergoing dialysis). These forms of renal bone disease are most objectively defined by double tetracycline-labeled quantitative histomorphometry, and quantitative histomorphometric criteria for classifying the specific form of renal bone disease (standardized nomenclature) have been published.^{16,17} Hence, the means by which renal osteodystrophy is first defined is divided into quantitative bone histomorphometry, then biochemical profiling, and finally, clinically. In addition, the challenge of defining osteoporosis, a common metabolic bone disease in the CKD population, is discussed. Finally, the therapeutic options that are available to treat specific forms of renal bone disease and osteoporosis associated with CKD are presented.

QUANTITATIVE BONE HISTOMORPHOMETRY

Double tetracycline-labeled quantitative bone histomorphometry is the “gold standard” for defining the specific forms of renal osteodystrophy.^{1,2,17,18}

BOX 205.1 HISTOMORPHOMETRIC FORMS OF RENAL BONE DISEASE**High or normal bone turnover**

Osteitis fibrosa cystica: increased osteoclast and osteoblast activity and peritrabecular fibrosis

Bone biopsy: increased bone turnover, increased number and activity of osteoblasts and osteoclasts, and variable amounts of peritrabecular fibrosis; increased osteoid with a “woven” pattern (as opposed to a normal “lamellar” pattern)

Etiology: secondary hyperparathyroidism

Low bone turnover

Osteomalacia: defective mineralization of newly formed osteoid

Bone biopsy: increased osteoid seam width, increased trabecular surface covered with osteoid, and decreased bone mineralization

Etiology:

Vitamin D related:

Vitamin D deficiency

Resistance to vitamin D

Non-vitamin D related:

Chronic metabolic acidosis: excess H^+ ions are buffered by bone HCO_3^- , which leads to release of calcium and a gradual reduction in bone calcium stores, subsequent bone demineralization, and eventually osteopenia; it is associated with an increased risk for recurrent fractures

Aluminum accumulation: most commonly related to aluminum-containing phosphate binder therapy and, recently, aluminum-containing antacids

Phosphate depletion

Adynamic or aplastic bone disease: most commonly seen in patients undergoing continuous ambulatory peritoneal dialysis; though characterized by low bone turnover, as in osteomalacia, there is no increase in osteoid formation

Bone biopsy: normal or decreased osteoid volume and reduced bone formation rate, reduced numbers of osteoblasts and osteoclasts

Etiology:

Sustained:

Total parathyroidectomy

Corticosteroid-induced osteoporosis

Diabetes mellitus: in patients with type 1, plasma parathyroid hormone levels tend to be lower than normal, which probably accounts for the lower than normal bone formation rate (speculative); lack of insulin may contribute by diminishing bone turnover in the uremic setting

Reversible:

Calcitriol and vitamin D analogues used to suppress the production of parathyroid hormone

Possibly oversuppression of parathyroid hormone production by cinacalcet

Exogenous calcium loading

Immobilization

Aluminum toxicity

Strontium

Diagnosis: aluminum loading must be excluded; bone biopsy is definitive.

Low to high bone turnover

Mixed uremic osteodystrophy

Calcific uremic vasculopathy

Dialysis-related β_2 -microglobulin amyloidosis (not exactly a metabolic bone disease)

Posttransplant bone disease

Osteoporosis

Age related

Hypogonadism

Corticosteroids

Heparin

Chronic acidosis

Poor nutrition

Vitamin D deficiency

Calcineurin inhibitors

TABLE 205.1
Stages of chronic kidney disease

Stage	Description	GFR (mL/min/1.73 m ²)
1	Kidney damage with a normal or increased GFR	>80
2	Kidney damage with a mildly decreased GFR	80-60
3	Kidney damage with a moderately decreased GFR	60-30
4	Kidney damage with a severely decreased GFR	30-15
5	Kidney failure	<15 (or dialysis)

GFR, glomerular filtration rate.

From Massry SG, Calum JW. K/DOQI clinical practice guidelines for bone metabolism and disease in chronic kidney disease. *Am J Kidney Dis* 2003;42(suppl 3):S10-135.

Several comprehensive atlases of renal bone disease have been published that describe in depth the normal bone remodeling process as measured by histomorphometry and then provide examples of bone biopsy specimens with a detailed descriptive analysis of each form of renal osteodystrophy.^{1,2} In addition, these atlases deal with histomorphometric data in post-renal transplantation bone disease and also provide histologic and clinical guidance for the diagnosis of osteoporosis in patients with CKD.

The KDOQI was the first attempt to provide broad guidelines for management of the abnormalities in calcium, phosphorus, PTH, and bone that accompany CKD,⁴ and more recently, a working group of the KDIGO expanded our understanding of the association of bone turnover, mineralization, and volume with the systemic vascular calcification that leads to the most prevalent cause of death in CKD patients: CKD-MBD.¹⁹

Bone biopsy should be considered in the following special clinical circumstances in patients with CKD^{1,2,10-12,18,19-25}.

- In those with fragility fractures because patients with all forms of renal osteodystrophy may sustain fractures and making the correct diagnosis is paramount in choosing the correct treatment. The diagnosis of osteoporosis, a very prevalent metabolic bone disease in patients with CKD, cannot be made in patients with stage 4-5/5D CKD by the bone mineral density (BMD) (World Health Organization [WHO]) criteria established for postmenopausal osteoporosis, nor by the presence of fragility fractures.^{9-12,20}
- In patients with an unexplained elevation in bone-specific alkaline phosphatase (BSAP) to exclude osteomalacia.
- In patients with severe secondary (e.g., tertiary) hyperparathyroidism before parathyroidectomy to be certain that no aluminum is present in bone. Parathyroidectomy before aluminum is removed will mitigate the ability of deferoxamine (DFO) to chelate and remove aluminum from bone.
- Before initiating DFO chelation to remove aluminum from bone in patients with suspected aluminum renal bone disease to be absolutely certain that aluminum is present in bone. Serum aluminum levels may not always reflect the presence of aluminum in bone.
- In patients with suspected adynamic renal bone disease based on biochemical profiles (hypercalcemia, low BSAP levels, lower intact PTH levels [<100 to 150 pg/mL], or a ratio of 1-84 to 7-84 [scantibodies] PTH <1.0).^{21,26,27}
- Before treating patients with stage 5/5D (dialysis) CKD with osteoporosis-specific pharmacologic agents for suspected osteoporosis because both osteomalacia and adynamic renal bone disease are diseases for which bisphosphonates or denosumab are not recommended. This opinion is based on the theoretic concept that it might be harmful to further reduce bone turnover in states of low bone turnover. Data would be needed to establish that antiresorptive agents may provide additional benefit for bone (further reduction in fracture risk) in patients with preexisting adynamic bone disease before these osteoporosis agents can be recommended.

TABLE 205.2
Relationship between biochemical profiles and key quantitative histomorphometrics in renal osteodystrophy in certain groups of patients

	iPTH	ALP/BSAP	BFR/BS	OV/BV	O.Th
High bone turnover					
	>10 times normal	Normal to increased	Increased	Variable, <15%	Normal to increased
	>3 times normal				
Low bone turnover					
Osteomalacia	Variable	Variable, increased	Reduced	>15%	Increased
Adynamic bone disease <2 times to reduced	Normal to reduced	Reduced to absent	<15%	Normal to reduced	
Mixed	Variable increased	Variable increased	Variable	>15%	Normal to increased
Osteoporosis	Normal (variable)	Normal (variable)	Normal	<15%	Normal

ALP, alkaline phosphatase; BFR, bone formation rate; BS, breaking strength; BSAP, bone-specific alkaline phosphatase; BV, bone volume; iPTH, intact parathyroid hormone; O.Th, osteoid thickness; OV, osteoid volume.

BIOCHEMICAL PROFILING

The laboratory tests that should be performed routinely in patients with renal disease, especially from stage 3 CKD onward, include serum calcium, phosphorus, PTH, BSAP, creatinine, chloride, carbon dioxide, and 25-hydroxyvitamin and 1,25-dihydroxyvitamin D levels.^{4,19,28-30}

Biochemical tests are performed for two distinctly separate reasons: (1) in an attempt to predict the histomorphometric findings in patients with CKD and (2) to make clinical management decisions to prevent the development of hyperphosphatemia, metabolic acidosis, and hyperparathyroidism.²²⁻²⁵

The use of biochemical profiling for characterizing the type of renal bone disease as defined by histomorphometry has value in groups of patients but loses both sensitivity and specificity in individual patient management. Table 205.2 condenses the generalities of the biochemical findings in CKD.²⁸ Previous publications have defined these biochemical-histologic relationships in much greater detail.^{4,19}

In general, patients with intact PTH (1-84) levels six times the upper limit of normal have a high probability of osteitis fibrosa cystica being present. In turn, patients who have low levels of PTH and BSAP have a higher probability of renal-related very low bone turnover or even adynamic or aluminum bone disease or low-bone turnover osteoporosis.^{4,22,30} Hence, although biochemical profiles are helpful in groups of patients, there is enough overlap that they may not accurately reflect bone histology in individual patients sufficiently to make bone biopsy unnecessary. For example, although PTH levels are ordinarily lower (<150 pg/mL) in patients with adynamic renal bone disease,^{4,19} published data suggest that patients with biopsy-proven adynamic renal bone disease may have intact PTH levels greater than 500 pg/mL.²¹ These situations may be associated with higher levels of catabolic PTH (7-84 PTH) and a 1-84:7-84 ratio of less than 1.0, although these ratios have been inconsistent in their discriminatory value.³¹ Even though it is biologically reasonable to assume that a patient with a 1-84:7-84 PTH ratio of less than 1.0 and a low BSAP has a high probability of having adynamic renal bone disease, data validating this are lacking, and thus biopsy is a necessity before major management decisions are made.

There are nonmodifiable as well as modifiable causes of adynamic bone disease (see Box 205.1).³² If the clinician suspects that the adynamic renal bone disease may be due, for example, to oversuppression of PTH by a vitamin D analogue or cinacalcet, it may be simpler to discontinue or reduce the dosage of the vitamin D analogue or cinacalcet and allow endogenous PTH levels to increase. However, clinical questions still remain unanswered if these modifications are made to allow the PTH level to rise. For example, does the increase in PTH translate into an improvement in bone turnover or a reduction in fracture risk in patients with iatrogenically induced adynamic renal bone disease? Bone histomorphometry, with measurement of bone formation rates and mineral apposition rates both before and after modification of factors that might be associated with adynamic bone disease, might be the most objective means by which to monitor the influence of any modification designed to alter rates of bone turnover.³³

Patients with renal osteodystrophy may move from one form of renal bone disease to another, and accompanying these transitions are distinct biochemical and histomorphometric changes that reflect the transition.^{19,28-30} For example, as CKD progresses through stages 3 to 5, there is progressive

development of secondary hyperparathyroidism that often resolves after renal transplantation and may then return again if the transplant is rejected and the patient returns to dialysis.^{19,22,30} Management decisions surrounding renal transplantation have been the topic of recently published texts.^{29,34}

The use of biochemical tests to manage individual derangements in chemical values that develop during the progression of CKD is a common means by which clinical nephrologists attempt to prevent the consequences of the development of hyperphosphatemia, metabolic acidosis, hyperparathyroidism, osteomalacia, and aluminum bone disease. The reader is referred to previously published details on management of the metabolic derangements that are seen in the progressive stages of CKD.^{4,19,22,30}

HYPERPHOSPHATEMIA AND HYPERPARATHYROIDISM

Hyperphosphatemia develops as the GFR declines because of the restricted capacity of the renal tubule to increase absolute urinary phosphorus excretion. Tubular reabsorption of phosphorus (TRP) decreases as the filtered phosphorus load decreases in an attempt to maintain the absolute urine phosphorus excretion rate and prevent hyperphosphatemia. Mediators of the decrease in TRP are the rising PTH and osteocyte-derived fibroblast growth factor-23 (FGF-23) levels.^{35,36} However, TRP can decline to only a limited degree even though serum PTH and FGF-23 levels continue to rise.

In the original description of the “trade-off hypothesis,” one of the causes of the progressive rise in endogenous PTH as GFR declines is retention of phosphorus and the subsequent adaptation to maintain a normal serum phosphorus level (to keep the calcium × phosphorus product normal and mitigate soft tissue calcification). The trade-off is the development of progressive secondary hyperparathyroidism.²⁵ Hence, in an ideal CKD management scenario, one restricts dietary phosphorus intake at certain levels of GFR to prevent the subsequent development of secondary hyperparathyroidism (which is now known to be related to multifactorial cascades: hypocalcemia, reduced renal production of 1,25-dihydroxyvitamin D, and a direct effect of elevated serum phosphorus and FGF-23 levels in reducing PTH production). Restriction of dietary phosphorus is difficult because phosphorus is ubiquitous in the food chain. In addition, serum phosphorus concentrations may vary because of the cellular shifts in phosphorus that occur after a glucose load or change in acid-base status. Thus mild and intermittent hyperphosphatemia may not be recognizable in stages 1 to 3 CKD. Persistent elevation of serum phosphorus may be seen only in stages 4 to 5 CKD, yet increased FGF-23 and secondary hyperparathyroidism precede this development. Hence, in both the KDOQI and KDIGO guidelines, the recommendation is to restrict dietary phosphorus and, if this is ineffective, to use one of the vitamin D analogues to suppress PTH values in stages 3 and 4 CKD when PTH levels rise to higher than 70 pg/mL (stage 3 CKD) or 110 pg/mL (stage 4 CKD) on more than two consecutive measurements. The purpose is to mitigate the effects of chronic elevation of PTH on skeletal health.

Suppression of PTH in patients with stage 5/5D CKD with the use of vitamin D analogues or cinacalcet has greater consensus in the nephrology community than does suppression of PTH in those with stage 3 or 4 CKD.^{37,38} Use of the pharmacologic modalities designed to suppress PTH levels in

patients with CKD is probably best directed by either nephrologists or specialists with a keen interest in metabolic bone disease. In patients with CKD, before or during the use of vitamin D analogues it is also very important to maintain the serum phosphorus concentration in a normal range to mitigate the potential for soft tissue calcification. A potential advantage of using cinacalcet as opposed to vitamin D analogues to suppress PTH levels is the finding that cinacalcet does not increase serum phosphorus or calcium levels in CKD patients.³⁹

Cinacalcet (initially at a dose of 30 mg/day with the dosage titrated to achieve an intact PTH level <250 pg/mL) normalized serum calcium and BSAP levels and, in contrast to the hyperphosphatemia that may be seen with the use of vitamin D analogues, lowered serum phosphorus concentrations as well.³⁹ Careful monitoring of PTH values is important if inhibitors of PTH production are used in patients with ESRD and severe secondary hyperparathyroidism. Although current guidelines suggest reducing PTH levels to less than 250 pg/mL in ESRD patients, there is a concern that oversuppression of bone turnover may lead to the development of adynamic bone disease if PTH levels are reduced too low.^{32,33} Currently, no universal consensus about the safe level of reduction of PTH has been reached. The KDIGO guidelines suggest watching the trend of PTH rather than making a clinical decision based on a single determination.

Surgical parathyroidectomy is indicated in patients with stage 5 CKD who have severe hyperparathyroidism that is not manageable with vitamin D analogues or cinacalcet. Parathyroidectomy is suggested in ESRD patients with persistent elevations in PTH levels greater than 800 pg/mL associated with persistent hypercalcemia, bone fractures, soft tissue calcification, or hyperphosphatemia.^{4,8,19}

OSTEOMALACIA

Osteomalacia, another form of low bone turnover, may also be seen in patients with CKD and has a variety of causes (Fig. 205.1). Even though accumulation of aluminum on the surfaces of osteoid is one of the reversible causes of osteomalacia, this disease may also be seen in the absence of aluminum accumulation and be related to either deficiency or insufficiency of 25-hydroxyvitamin D levels, low 1,25-dihydroxyvitamin D levels, chronic hypophosphatemia, or chronic metabolic acidosis.

Specific quantitative histomorphometric criteria have been established for the classification of osteomalacia.^{1,17,18} Although low bone turnover may be seen in a variety of disease states, including osteoporosis, osteomalacia *per se* has very specific diagnostic criteria.

Because all forms of osteomalacia have a distinct treatable etiology, the correct diagnosis is essential for effective therapy. Fragility fractures may develop in patients with osteomalacia and osteoporosis. As will be discussed, bisphosphonates are contraindicated in patients with osteomalacia. Thus it becomes especially important to differentiate osteoporosis from osteomalacia, especially in a patient with ESRD and fragility fractures. Here, too, double tetracycline-labeled bone biopsy is the single most objective means of making the differential diagnosis.

Fig. 205.1 Osteomalacia: osteoid (pink) surface greater than 80%, osteoid thickness greater than 12 μ m, and mineralization lag time longer than 100 days. (From Miller PD, Huffer W. Renal osteodystrophy. In: Schrier RW, Bennett W, editors. *Essential atlas of nephrology and hypertension*. 2nd ed. Philadelphia: Current Medicine; 2004.)

Osteomalacia caused by very low levels of 25-hydroxyvitamin D can be treated by vitamin D supplementation, which leads to an increase in 25-hydroxyvitamin D levels to greater than 30 ng/mL; this will be accompanied by a reduction in and ultimately normalization of the serum BSAP level. To increase vitamin D levels to normal in the elderly population, 50,000 units of vitamin D₂ or D₃ may be required once or twice per week for a protracted time to be effective. Monitoring BSAP, 25-hydroxyvitamin D, PTH, and serum calcium levels must be done periodically, with the vitamin D replacement titrated accordingly.

Although the prevalence of aluminum bone disease has decreased with the less frequent use of aluminum-containing phosphate binders, it is still surprisingly common. The KDOQI guidelines suggest maintaining the aluminum concentration in dialysate fluid at less than 10 mg/L. In addition, the KDOQI guidelines recommend treating symptomatic ESRD patients with either basal serum aluminum levels greater than 60 mg/L or a rise in serum aluminum of 50 mg/L or more after a DFO challenge test. Treatment of aluminum bone disease is long-term (4 to 6 months), with DFO doses of 5 mg/kg administered intravenously over a period of 1 hour before hemodialysis, one to two times per week.

Before therapy with DFO, one should be as certain as possible that aluminum bone disease is present. Here again, bone biopsy with aluminum staining is diagnostic. In addition, repeating bone biopsy after completion of the DFO treatment course is the most sensitive way to be certain that the aluminum has been removed. It is not uncommon to have normal basal and post-DFO challenge serum aluminum levels and yet still have abundant aluminum covering the osteoid surfaces.

ADYNAMIC RENAL BONE DISEASE

Adynamic renal bone disease is an increasingly prevalent form of renal osteodystrophy that may be associated with fragility fractures, low BMD, and variable biochemical profiles (Fig. 205.2).^{18,19,21,30,33} Adynamic bone disease was initially seen predominantly in diabetic ESRD patients being treated with peritoneal dialysis, even in those who had not received interventions to reduce PTH levels. However, the prevalence of this disease seems to be increasing.

Although some forms of adynamic bone disease have no apparent cause, there may be modifiable as well as nonmodifiable forms.³² It is probable that oversuppression of PTH, whether by vitamin D analogues, cinacalcet, or parathyroidectomy, may lead to some forms of adynamic bone disease. In theory, forms of adynamic bone disease that are induced by pharmacologic suppression of PTH may be reversible once the agent responsible is removed. However, in some situations, adynamic bone disease is seen without an identifiable etiology, and these forms are very problematic because severe fragility fractures develop in many of these patients.^{40,41} In addition, biochemical profiling may not be sensitive or specific enough to make a diagnosis of adynamic bone disease in an individual patient. Thus bone histomorphometry becomes a necessity in these patients.

Fig. 205.2 (a to d) Adynamic renal bone disease. (From Miller PD, Huffer W. Renal osteodystrophy. In: Schrier RW, Bennett W, editors. *Essential atlas of nephrology and hypertension*. 2nd ed. Philadelphia: Current Medicine; 2004.)

In patients with severe CKD who are experiencing fractures and have low BMD and clinical reasons suggesting osteoporosis, biopsy is often a necessity before initiating bisphosphonate treatment or, for that matter, any antiresorptive agent to reduce fracture risk. Use of an agent that reduces bone turnover in patients who already have preexisting low bone turnover could possibly be detrimental.^{42,43} Oversuppression of bone turnover leading to bone fragility has been suggested by anecdotal data but remains an unproven hypothesis.⁴²⁻⁴⁵ It is also plausible that bisphosphonates can mitigate vascular calcification.⁴⁶⁻⁴⁸ However, in ESRD patients in whom adynamic bone disease is defined by quantitative bone histomorphometry, bisphosphonates should not be given to augment bone strength.^{19,49,50}

METABOLIC ACIDOSIS

Metabolic acidosis, most commonly caused by the accumulation or reduced excretion of organic anions, may develop in patients with CKD. It is seen most often when the GFR reaches less than 30 mL/min. A non-anion gap metabolic acidosis (renal tubular acidosis [RTA]) may be seen at any level of GFR and in patients without any reduction in renal function. Either proximal (rare) or distal (common) RTA can lead to either osteomalacia or osteoporosis.⁵¹⁻⁵³ In patients with CKD, the serum bicarbonate level should be measured and, if necessary, maintained at a level higher than 22 mmol/L with alkali salts. However, it is important to not use citrate as the alkali salt because it enhances the intestinal absorption of aluminum.

OSTEOPOROSIS

Although osteoporosis is not listed in the literature as a form of renal osteodystrophy, the consideration that some form of osteoporosis rather than a renal-related metabolic bone disease is causing fractures will take on more significance in clinical practice. Osteoporosis may develop in patients with CKD for many reasons.^{10-12,15} As patients with CKD live longer, more will also have an increased risk for the development of osteoporosis.

How does one make the diagnosis of osteoporosis in patients with CKD? All forms of renal bone disease may be associated with fragility fractures or low BMD. The recent KDIGO working group does support use of the WHO criteria for the diagnosis of osteoporosis in stages 1 to 3 CKD.¹⁹ However, neither fractures nor the WHO criteria (BMD T-score of -2.5 or below) can be used with certainty to make a diagnosis of osteoporosis in patients with stage 4-5/5D CKD. Because biochemical profiling cannot clearly discriminate among the various forms of renal osteodystrophy with certainty, it also cannot be used to make a diagnosis of osteoporosis. Hence, it becomes a necessity to differentiate between the renal osteodystrophies and osteoporosis by quantitative bone histomorphometry, especially if the physician thinks that the patient has osteoporosis and is contemplating using osteoporosis-specific pharmacologic agents designed to improve bone strength and reduce the risk for fracture.²⁴ Although hormone replacement therapy (HRT), selective estrogen receptor modulators (SERMs), and calcitonin can reduce fracture risk in postmenopausal women, older men, and patients with glucocorticoid-induced osteoporosis, they may have limitations in patients with CKD. HRT and SERMs increase the risk for venous thrombosis, and there is no evidence that calcitonin reduces the risk for nonvertebral or hip fractures. These latter forms of fragility fractures are common in patients with CKD. Thus physicians caring for patients with CKD who also have fragility fractures, especially ones associated with high mortality, often ask about the use of bisphosphonates or even teriparatide (recombinant human 1-34 PTH) for patients with CKD.

The Food and Drug Administration (FDA) advised against using bisphosphonates in patients with a creatinine clearance lower than 30 to 35 mL/min. This warning is not a contraindication to the use of bisphosphonates in patients with stages 4 to 5 CKD but is based mostly on the lack of evidence of safety in patients with more severe CKD and on data from animal studies indicating that high oral doses of bisphosphonates may induce a renal lesion and reduced GFR. The exception is intravenous zoledronic acid (Reclast), which is contraindicated in those with a GFR lower than 35 mL/min.

Recent *post-hoc* pooled analyses obtained from the risedronate clinical trial data set indicate that daily doses of risedronate (5 mg/day) are safe (do not alter serum creatinine concentrations) and effective (reduction in incident vertebral fracture risk) in patients with GFR levels between 15 and 30 mL/min.⁵⁵ In addition, a *post-hoc* analysis from the alendronate postmenopausal registration trials also demonstrated that the daily formulations of alendronate are also safe and effective in reducing all clinical fractures in women with an estimated GFR as low as 15 mL/min.⁵⁶ Similar *post-hoc* data have also been reported from the raloxifene postmenopausal registration trial.⁵⁷ These *post-hoc* analyses need to be confirmed by prospective studies; however, the data do suggest that FDA-approved doses of oral bisphosphonates are safe and effective even in patients with stage 4 CKD.⁵⁸ These data may not apply to patients with stage 5/5D CKD, those with ESRD, or the post-renal transplant population.

Intravenous bisphosphonates, zoledronic acid, and ibandronate may have a greater potential for inducing abrupt and mostly short-term changes in renal function and, for these reasons, should be avoided even off-label in patients with a GFR lower than 35 mL/min.⁵⁹ Intravenous zoledronic acid is now contraindicated for use in patients with a GFR lower than 35 mL/min because of postmarketing reports of 25 cases of acute renal failure.⁶⁰ In contrast, in a prospective analysis of patients at high risk for renal failure, intravenous ibandronate given as the registered injection or a slower 5-minute infusion did not induce acute renal failure.⁵⁹ A clinical question often arises about what dose of oral bisphosphonate should be considered off-label in patients with stage 5 or 5D CKD who have osteoporosis. Here we have no evidence and only opinion exists. Because of the known pharmacokinetics of oral bisphosphonates, using 50% of the dose prescribed for patients with stage 4 CKD and a normal GFR seems reasonable while recognizing that bone affinities, bone retention time, and bone accumulation may be very different in those with GFR values lower than 15 mL/min or even among the various oral bisphosphonates.

What about the use of teriparatide in patients with CKD? There should be no reason why teriparatide should not be effective in reducing the risk for both nonvertebral and vertebral fractures in patients with stages 1 to 3 CKD. Even in elderly women and men with osteoporosis, who often have secondary hyperparathyroidism because of vitamin D insufficiency, teriparatide appears to be effective. Most clinicians do not measure PTH levels at baseline before initiating teriparatide, yet elevations are common in the elderly, who often also have reductions in the GFR. Indeed, recent *post-hoc* data from the teriparatide fracture prevention trial suggested that it is also safe and effective down to GFR levels of 30 mL/min.⁶¹ It is certainly not suggested that patients with stage 4-5/5D CKD should receive teriparatide for severe osteoporosis. In the author's opinion, in patients with these severe degrees of CKD, bisphosphonates should be used only in those with osteoporosis and fractures.

CONCLUSION

Renal osteodystrophy is a heterogeneous group of metabolic bone diseases associated with declining GFR values. There are many causes and clinical manifestations that often cannot be distinguished from one another without quantitative bone histomorphometry, especially in patients with stage 4-5/5D CKD. Once the diagnosis is clear, all forms of renal osteodystrophy have many reversible causes; some remain "idiopathic," however. Newer therapies such as vitamin D analogues or cinacalcet can mitigate one form of renal osteodystrophy: secondary hyperparathyroidism. Osteoporosis also occurs in patients with CKD and is associated with clinical findings not easily indistinguishable from those of "renal bone disease," fractures, and low bone mass. Nevertheless, osteoporosis does occur in CKD and may be amenable to interventions designed to reduce fracture risk in patients with osteoporosis and normal renal function. The recent KDIGO report has expanded the relationships between bone mineralization, turnover, and volume to link the bone derangements in CKD to systemic vascular calcification (CKD-MBD). Physicians need guidance on how to diagnose and treat osteoporosis in their CKD patients, especially those with stage 4-5/5D CKD, for which evidence-based data are nearly nonexistent.

■ MARGARET SETON

- Paget disease of bone is a focal disorder of bone remodeling characterized by accelerated bone resorption coupled to formation that results in enlargement and deformity of bone.
- The disease may occur in one or more bones; has a predilection for the skull, spine, pelvis, and lower extremities; and is a disease of the adult skeleton that increases in prevalence with aging and is marked by a slight male preponderance.
- Familial and sporadic cases are reported. Geographic prevalence of the disease varies throughout the world.
- The pathogenesis is unknown; although genetic determinants have now been recognized, the environmental triggers remain undefined.
- Clinical complications include pain, deformity, fracture, and nerve compression syndromes; metabolic consequences are reported. Rarely, an osteosarcoma arises in pagetic bone.

HISTORY

In 1876, Sir James Paget presented a paper titled "On a Form of Chronic Inflammation of Bones (Osteitis Deformans)" in which he detailed the progressive, crippling deformity of bone that would be called Paget disease of bone.¹ That it existed before this time is evidenced by paleoarcheologic findings of thickened skulls consistent with Paget disease in some Neanderthal remains and by excavations of early Anglo-Saxon graveyards in northern England.²

EPIDEMIOLOGY

Paget disease of bone is a disorder of the adult skeleton and is not seen in children. This observation was confirmed in autopsy series in Germany and England in which pagetic bone was identified only in persons older than 40 years; its prevalence ranged from 3.0% to 3.7%. Population studies undertaken since that time to determine the prevalence of this disease have depended largely on screening radiographs and questionnaires. Because of its predilection for the axial skeleton and proximal end of the femurs, radiographs of the kidney/ureter/bladder, taken as routine admission films or for other indications such as abdominal pain or kidney stones, formed the basis of many population studies to determine prevalence. Using this protocol in England, the radiographic prevalence of Paget disease was 5.4% in persons aged 55 and older.³ In the United States, using the First National Health and Nutrition Examination Survey database, the prevalence of radiographic Paget disease of the pelvis in the population aged 55 to 74 years was reported to be around 2% and was more frequent in residents of northeastern states and in whites.⁴ In a 1982 postal survey across western Europe, Detheridge and colleagues⁵ mapped the prevalence of Paget disease from 1416 replies; they noted it to be most prevalent in Great Britain, where geographic clusters occurred. In addition, Paget disease is common in regions of France, Spain, Italy, and other western European countries and in Australia and New Zealand. It is unusual in Norway and Sweden and rarely reported in India and the Far East. The prevalence of Paget disease increases with age. Between 10% and 40% of persons with Paget disease report a family history of this disorder. Males are affected slightly more than females at a ratio of 1.4:1.^{6,7} More recent epidemiologic data suggest a decline in both the prevalence and severity of this disease.^{8,9}

PATHOGENESIS

Etiology

Paget disease is thought to reflect a genetic disorder that is autosomal dominant in transmission with variable penetrance. The most prevalent mutation accounting for both familial and sporadic Paget disease is in the gene *sequestosome 1* (*SQSTM1*), with more than 20 mutations now described in or proximal to the ubiquitin-associated (UBA) domain of the protein product p62.¹⁰ Polymorphisms in the genes affecting osteoclast-signaling pathways are also thought to play a role in facilitating the expression of Paget disease in bone. Because Paget disease exists in many persons without the *SQSTM1* mutation and the mutation is reported in persons without evidence of Paget disease, other environmental determinants such as viruses, toxins, trauma, and rural exposures have been explored as predisposing factors.¹¹

Genetic factors

In 2002, scientists studying a French-Canadian cohort of patients with Paget disease described a mutation in the gene *SQSTM1* on chromosome 5q35 that occurred in 46% of patients with familial Paget disease and in 16% of patients with sporadic Paget disease.¹² The most common mutation, P392L, occurred in the UBA domain of p62 and was confirmed in patients with Paget disease in other countries, albeit at lower rates.¹³ These *SQSTM1* mutations seem to occur in a limited number of shared haplotypes, thus suggesting a founder effect.¹⁴ This observation is consistent with the epidemiology of Paget disease and the European origins of this disorder. Unresolved is whether sporadic Paget disease of bone, in which the prevalence of germline mutations in *SQSTM1* is low, may be due to a somatic mutation.¹⁵

Work is under way to understand how these mutations in *SQSTM1*/p62 affect ubiquitin binding and result in osteoclast activation and bone resorption.¹⁰ Increasingly, autophagy is postulated to play a role in Paget disease, and evidence of inclusion bodies in pagetic osteoclasts points toward this mechanism of disease, both in animal models and in humans.¹⁶

Insight into this has been gleaned from a rare degenerative disease, IBMPFD (inclusion body myopathy, Paget disease, and frontotemporal dementia), in which mutations in the valosin-containing protein (VCP) gene result in disruption of the ubiquitin-proteasome degradation pathways.¹⁷ However, the etiology of these inclusion bodies and their identify remain controversial.¹⁸

In the clinical realm, efforts to correlate genotype with phenotype suggest that truncating mutations in patients with Paget disease may result in more severe disease characterized by earlier onset and more affected bones. The *SQSTM1* mutation by itself does not seem to predict an earlier age at onset or a particular phenotype.^{19,20}

Environmental factors

A number of environmental factors have been proposed to be of importance in Paget disease of bone. The most persuasive of these factors is exposure to paramyxoviruses, specifically canine distemper virus and measles. Despite evidence that measles virus nucleocapsid can promote a pagetic phenotype in osteoclasts and to some degree in mouse models,²¹ there is no proof that these viruses are causative. Still, work from Kurihara and colleagues²² elucidated a mechanism whereby infection can augment osteoclast activity, perhaps by increasing local interleukin-6 production. The marrow itself may provide a microenvironment permissive of Paget disease.²³ Pet ownership, exposure to well water, urban versus rural upbringing, and sibship size are proving inconsistent determinants of Paget disease at this time.²⁴

Fig. 206.1 Histopathology of pagetic bone. Irregular cement lines (arrow) formed by the disorganized deposition of bone result in a characteristic mosaic pattern.

Fig. 206.2 Histopathology of pagetic bone. Note the numerous, large multinucleated osteoclasts (arrowhead) active in bone resorption, whereas osteoblasts (arrow) respond with bone formation. Highly vascular fibrous connective tissue is present, replacing normal marrow.

Histopathology

Paget disease of bone is mediated largely by abnormal osteoclasts. Evidence that the osteoclast plays a pivotal role in the pathogenesis of Paget disease is based on the following:

- Pagetic osteoclasts express a bizarre phenotype, contain intranuclear inclusions, and are hypersensitive to physiologic amounts of vitamin D.
- The earliest clinical lesion is lytic.
- Treatment of the osteoclast is sufficient to restore normal rates of bone remodeling.

The accelerated rate of bone resorption seen in patients with Paget disease is accompanied by bone formation, a process that results in pagetic bone that is thickened but structurally compromised. This structural incompetence is due to the abnormal deposition of both woven and lamellar bone. The woven bone is weaker than normal; although the units of lamellar bone increase bone mass, they are deposited in an architectural pattern that is biomechanically unsound. Histologically, this is manifested as randomly arranged units of lamellar bone delineated by cement lines that form the pathognomonic “mosaic” pattern (Fig. 206.1). Other secondary changes include increased vascularity, peritrabecular fibrosis, and loss of normal marrow elements over time (Fig. 206.2). Despite large fluxes of calcium in and out of bone, there tend to be no perturbations in the measured serum calcium or phosphate concentrations in otherwise healthy individuals.

CLINICAL FEATURES

Signs and symptoms

Sir Paget wrote, “It begins in middle age or later, is very slow in progress, may continue for many years without influence on the general health, and may give no other trouble than those which are due to the changes of shape, size and direction of the diseased bones.”¹ Many patients with Paget disease of bone are asymptomatic and the diagnosis is made incidentally because of an isolated elevation in the serum alkaline phosphatase level or because pagetic bone is noted on a screening radiograph ordered for another reason. Other patients with Paget disease may suffer crippling deformities of bone (Fig. 206.3), disfigurement (Fig. 206.4), pain, fracture, nerve compression

Fig. 206.3 Bowing of the right femur leading to shortening of the right lower limb.

Fig. 206.4 Paget disease of the maxilla resulting in the characteristic facial deformity known as leontiasis ossea. Note also hypertrophy of the right temporal artery, which can potentially be mistaken for temporal arteritis.

syndromes, and impaired quality of life, depending on the bones affected. Pain in patients with Paget disease of bone is derived from several sources: from the bone itself, from the consequence of encroachment on proximal structures, and from secondary osteoarthritis of joints provoked or in part driven by overgrowth of the pagetic bone.²⁵

Skeletal sites

Paget disease may affect any bone and may be monostotic or polyostotic. It has a predilection for the skull, lumbosacral spine, pelvis, and femur but is commonly noted in other bones of the appendicular skeleton as well. When the disease affects the skull, hearing loss, headache, and visual disturbance may ensue; the skull may “settle” and soften in a “tam-o-shanter” shape that can result in basilar invagination, cord compression, and hydrocephalus (Fig. 206.5). Vertebral involvement with overgrowth of bone or compression fractures (or both) may be manifested as spinal cord lesions, isolated radiculopathy, spinal stenosis, and cauda equina syndromes (Fig. 206.6). The heightened vascularity of bone has also been reported to cause vascular steal syndromes (Fig. 206.7). When Paget disease involves bone proximal to a joint, patients usually have pain, limitation of motion, and early osteoarthritic changes at that site (Fig. 206.8). The consequence of the bowing deformities of limbs is frequently degenerative changes at multiple sites as a result of misalignment of joints and altered weight bearing. The clinical consequences of these problems include instability of gait, falls, and fracture.

IMAGING

Radiography and bone scintigraphy record the abnormal bone turnover and selective bony involvement so characteristic of Paget disease. Bone

Fig. 206.5 This magnetic resonance image shows a grossly thickened pagetic skull with evidence of basilar invagination and compression of the lateral ventricle of the brain.

scintiscans are particularly useful in defining the extent of disease (Fig. 206.9), whereas conventional radiographs define important information about the anatomy of the pagetic bone. Classic radiographic features of Paget disease include thickened cortical bone and mixed lytic-sclerotic lesions that evolve over time with subsequent distortion and overgrowth of affected bone. Lesions usually begin in the subchondral area and are continuous (progressing without skip lesions through that bone); cortical tunneling and trabecular thickening may be present (Fig. 206.10).²⁶ Plain films are diagnostic in most instances and are useful in assessing the complications of Paget disease and in evaluating whether the disease is in its incipient lytic phase or has progressed (Fig. 206.11). As the weight-bearing bones bow, small fissure fractures may occur in cortical bone (Fig. 206.12). These fractures usually occur on the convex portion of the femur, in contradistinction to the pseudofractures of osteomalacia (Looser zones), which occur on the concave portion. Paget disease of bone does not cross normal articular surfaces, although it may bridge bony calluses. It does not metastasize, and it is distinctly unusual to identify new bone involvement with Paget disease over time. The environmental or genetic determinants of this remain unclear. Serial bone scintiscans and radiographs have been reported to show

Fig. 206.7 Paget disease producing a right deformity of the skull, deafness (see the hearing amplifier device in the right ear), and apathy as a result of vascular steal syndrome.

Fig. 206.6 Paget disease of the spine. (a) Slipped pagetic vertebra narrowing the neural foramen. (b) Bulging of an intervertebral disk leading to spinal stenosis; the stenosis is less severe at the level of the pagetic vertebra.

Fig. 206.8 Standing anteroposterior radiograph of the knees taken in a flexed position. Marked pagetic involvement of the left tibia has resulted in end-stage degenerative changes in that knee. Note the thickened bone, mixed lytic and sclerotic lesions, and heightened trabecular markings. The right lower extremity and left fibula are unaffected.

improvement with treatment of Paget disease of bone and may be useful in monitoring some patients with pagetic lesions and normal biochemical parameters and those with predominantly lytic lesions of bone (Fig. 206.13).

LABORATORY FINDINGS

Serum alkaline phosphatase is a useful measure of active Paget disease of bone when its origin has been identified as bone. Although historically an elevated serum alkaline phosphatase level reflected the extent and activity of skeletal disease, increasingly patients are being found to have normal alkaline phosphatase levels.²⁷ This is attributed to a decrease in the prevalence and severity of Paget disease being reported²⁸ and an increase in monostotic disease.²⁹ Some patients with long-standing Paget disease will have little or no elevation in the serum alkaline phosphatase value or uptake by bone scintigraphy, thus suggesting end-stage Paget disease that is sclerotic and biochemically quiescent. Recent studies suggest that other markers of bone formation, including bone-specific alkaline phosphatase and procollagen type I N-terminal propeptide, may prove useful in screening for pagetic activity and in monitoring therapy with the bisphosphonates and that markers of bone resorption such as urinary N-telopeptides may reveal early (e.g., 10 to 14 days) and late responses to therapy. However, investigations over the years have failed to demonstrate any marker of bone turnover that is superior to serum alkaline phosphatase in most patients.³⁰

DIFFERENTIAL DIAGNOSIS

Paget disease is usually well defined by the clinical picture and the classic findings on bone scans, radiographs, and computed tomography. In the age group affected by this disease, osteoporosis and cancer are also prevalent, and it is prudent to remember that these diseases may coexist and affect skeletal health. Because of the variable manifestations of Paget disease in both the lytic and blastic phases, there are a few circumstances in which tissue biopsy may be required to prove the diagnosis. New lesions noted on bone scintiscan at any site, not present or suspected on earlier bone scans, require further evaluation. Metastases rarely occur at sites of pagetic bone, so comparison of a new bone scintiscan with a baseline bone scintiscan may prove useful. In cases in which the diagnosis of Paget disease of bone remains unclear and in cases in which a pagetic osteosarcoma is suspected on the basis of increasing pain and soft tissue swelling, magnetic resonance imaging may better define the soft tissue anatomy and address whether effacement of normal marrow or structures or cortical disruption by a mass is present.

Fig. 206.9 A technetium-99m MDP (methylenediphosphonate) bone scan shows polyostotic Paget disease involving the sternum, right scapula, two lumbar vertebral bodies, and right hemipelvis. Early pagetic disease may be involving the right side of the skull as well.

COMPLICATIONS AND NATURAL HISTORY

The most devastating long-term complication of Paget disease of bone is osteosarcoma. This complication is rare and occurs in less than 1% of persons with known disease; it carries a distinct genetic signature and accounts for many of the sarcomas in the elderly.³¹ Outcomes are usually poor. Other complications of Paget disease result from the overgrowth and deformation of bone and include neurologic compression syndromes, disfigurement or periodontal complications as a result of pagetic bone affecting the mandible or maxilla, vascular steal syndromes, high-output heart failure, headache, and hearing loss. In addition, patients with Paget disease seem to be more vulnerable to osteoarthritis and its attendant morbidity, hyperparathyroidism, renal stones, and gout.³² Anecdotal reports suggest that angiod streaks and Peyronie disease may be more common in persons with Paget disease. A study from the United Kingdom suggested that all-cause mortality in patients with Paget disease may be increased in comparison to age-matched controls,³³ although this finding was not corroborated in the United States.³⁴

TREATMENT

Treatment should be undertaken with the aim of easing pain, preventing progression of the disease, and improving the quality of bone. Treatment is indicated in patients with polyostotic Paget disease who require prolonged bed rest or are immobilized in a cast for other reasons, a state that may exacerbate the lytic lesions in bone. Treatment is also indicated for metabolic complications of Paget disease such as high-output cardiac failure and for hypercalcemia or nerve compression syndromes, as well as for patients in whom surgery on pagetic bone is anticipated. Treatment options and regimens are listed in Table 206.1.

Fig. 206.10 Lateral radiograph of the lower extremity. Classic changes of Paget disease are present in the bowing deformity of the tibia, marked cortical thickening, and mixed lytic and sclerotic lesions. The fibula is spared.

Fig. 206.11 This lateral radiograph of the skull shows the early, lytic phase of Paget disease known as osteoporosis circumscripta (arrows mark the leading edge).

Fig. 206.12 Lateral radiographs of the left femur before (a) and after (b) fracture. (a) Cortical incongruities or fissure fractures are present on the convex surface of this pagetic femur. They were asymptomatic for 15 years and showed no resolution with bisphosphonate treatment. (b) In 2005 the patient suffered an atraumatic fracture at this site. The fracture is a classic "chalk stick" fracture characteristic of Paget disease.

Fig. 206.13 Sequential radiographs of a pagetic tibia demonstrating the natural progression of the advancing osteolytic fronts within the bone.

Bisphosphonates

With development of the bisphosphonates and their promise of sustained clinical remission, these drugs have become the agents of choice for the treatment of Paget disease. The newer generation nitrogen-containing bisphosphonates reflect a trend toward more potent suppression of bone resorption without impairment of mineralization at therapeutic doses. The mechanism of action is inhibition of farnesyl diphosphate synthase, an enzyme in the mevalonate pathway critical in the prenylation of small proteins that facilitate cytoskeletal reorganization and bone resorption.³⁵ Tiludronate and clodronate are also bisphosphonates that work through another mechanism of action to promote osteoclast apoptosis and inhibit bone resorption; they are less potent, yet effective in treating Paget disease. These bisphosphonates are variably accessible in countries around the world, their distribution determining in large part choice and utilization.

Zoledronic acid is the most effective bisphosphonate for the treatment of Paget disease of bone; it secured a durable remission in patients as measured by suppression of serum alkaline phosphatase levels and biochemical

TABLE 206.1
Medications for the treatment of Paget disease of bone*

Medication	Dose and regimen	RCT	Reference
Calcitonin	50-100 IU subcutaneous daily Comments: Well tolerated with mild nausea and flushing expected. Eases pain often, but no sustained efficacy; nasal spray is not FDA approved in the USA but may be effective at 400 IU daily	No	J Clin Invest 1971;50:1927-40 Calcif Tissue Int 1991;49:164-7
Etidronate	5 mg/kg daily by mouth for 6 mo Comments: Osteomalacia, fractures, worsening lytic lesions, and pain	Yes	N Engl J Med 1973;289:1379-84
Alendronate	40 mg daily on rising by mouth for 6 mo Comments: CVS ProCare pharmacy distributes this, often at cost to the patient and excessive time to the physician (888-900-1500)	Yes	J Clin Endocrinol Metab 1996;81:961-7 Bone 2004;34:747-54
Tiludronate	400 mg daily by mouth for 3 mo Comments: Less potent than the nitrogen-containing bisphosphonates	Yes	Arthritis Rheum 1995;38:851-8 Postgrad Med J 1997;73:496-502
Risedronate	30 mg daily on rising by mouth for 2 mo Comments: Readily available, well tolerated	Yes	Am J Med 1999;106:513-20 Calcif Tissue Int 2004;75:189-96
Pamidronate	30 mg daily IV over a 4-hour period on 3 consecutive days (90 mg total dose) Comments: Infusion time may be shortened; regimens vary widely worldwide	Yes	Bone 2004;34:747-54 Clin Rheumatol 1994;13:39-44
Zoledronate	5 mg IV over a 15-minute period Comments: Reassessment rather than annual infusions are encouraged	Yes	N Engl J Med 2005;353:898-908 Ther Clin Risk Manag 2007;3:913-8 J Bone Miner Res 2007;22:142-8

*These are approved by the FDA; in other countries, clodronate, ibandronate, neridronate, and alpadronate are available for the treatment of Paget disease. FDA, U.S. Food and Drug Administration; IV, intravenously; RCT, randomized controlled trial.

markers of bone turnover into the normal range. It is given once at a dose of 5 mg by infusion over a 15-minute period, is well tolerated, and seems to be more effective in patients who have previously been treated with other bisphosphonates or have shown resistance to them.

In Paget disease, for which treatment is intermittent and confined mostly to the population older than 55 years, complications of treatment are infrequent and the benefits tend to be measurable.³⁶

Whether bisphosphonate treatment will prove useful in terms of long-term outcomes in the lives of patients with Paget disease is less unclear. In the PRISM trial in England in which aggressive versus symptomatic treatment of patients with Paget disease was studied,³⁷ no difference was found in outcomes in the two groups as measured by fracture rate, quality of life, or other complications of the disease. Perhaps this should have been anticipated inasmuch as treatment cannot restore the structural integrity of a deformed pagetic limb, reverse the evolution of arthritis in a pagetic joint, or restore hearing once the skull is overgrown. Treatment can, however, ease neurologic syndromes, diminish blood flow through pagetic sites, enhance the deposition of more normal bone, and ease pain; it may prevent disease progression, promote healing of radiographic lesions in some, and normalize serum alkaline phosphatase in many. Patients should be treated with vitamin D and calcium concurrently.

Other drugs

Calcitonin has been used widely for the treatment of Paget disease since the 1970s. Its waning efficacy over time, the absence of durable remission, and the discomfort of the injection limit more extensive use of this drug. Calcitonin is relatively safe, eases pain, and improves bone lesions, so it continues to have a role in infirm geriatric patients who are intolerant of or have contraindications to bisphosphonates and in whom transient relief from Paget disease is sought. There is a case report of the use of denosumab for the treatment of a patient with Paget disease.³⁸

Supportive therapy

Failure of the bisphosphonates to ease pain may not signify resistance to the drug but may indicate pain originating from other sources.²⁵ Many patients afflicted with Paget disease of bone are elderly and suffer from arthritic pain, loss of hearing, sciatica, and instability of gait from other causes. Analgesics, bracing, gait training, and walking aids may be beneficial

Fig. 206.14 Lateral radiographs of the right femur before (a) and after (b) bisphosphonate therapy. (a) Postoperative lytic lesions are seen in the pagetic bone around the rod placed to stabilize the fracture site. (b) Note the radiographic evidence of healing after therapy with alendronate.

when treatment of the pagetic bone fails to ease their distress. Hearing aids and glasses are prescribed when appropriate. Physical therapy and therapy aimed at the psychosocial issues of aging may also prove useful.

Surgery

When end-stage osteoarthritis of the hip or knee occurs, orthopedic surgery may prove beneficial in restoring independence and easing pain. Paget disease has distinct orthopedic issues, including the quality and vascularity

of bone, the bowing deformity in the long limbs, or distortion of the acetabulum with or without protrusio. Anticipating surgery by pretreating patients with bisphosphonates is thought to improve outcomes by diminishing the vascularity of bone, restoring normal lamellar bone formation, and preventing postoperative lysis of bone (Fig. 206.14). Clinical data are sparse, and no randomized controlled trials have evaluated blood loss, healing, or bony ingrowth in patients pretreated with bisphosphonates versus controls. Heterotopic bone formation may be more common in patients with Paget disease undergoing total hip replacement, but the outcomes are generally excellent for both total hip and total knee replacement. Satisfaction with corrective osteotomies for severe limb deformity in Paget disease is less consistent, but the surgery may be beneficial for some.³⁹

CONCLUSION

Paget disease of bone is a focal disorder of the aging skeleton that may be expressed as a familial or sporadic disease and may affect one or many bones in a given person. The geographic and familial clusters of the disease have led to the identification of environmental and genetic determinants of Paget disease. No cure is available, but there is effective treatment that will ease the pain and nerve compression syndromes caused by pagetic bone, normalize the serum alkaline phosphatase level in many, and hopefully prevent progression of early Paget disease. Therapeutic advances in the past 25 years have made these goals feasible.

HERITABLE DISEASE AND TUMORS
OF BONE AND CONNECTIVE TISSUE

207

Gaucher disease

■ PHILIPPE ORCEL ■ ROSE-MARIE JAVIER

- Gaucher disease results from the accumulation of glucosylceramide in organs and tissues throughout the body in characteristic storage cells, namely, "Gaucher cells."
- The most common inherited glycolipid storage disease, Gaucher disease is a heterogeneous disorder with three clinical phenotypes:
 - Type 1, the adult, nonneuronopathic chronic form, is characterized by organomegaly, hematologic disorders secondary to hypersplenism, bone lesions attributable to medullary infiltration by Gaucher cells, and no central nervous system involvement.
 - Type 2, the infantile, neuronopathic acute form, is manifested as early involvement of the brain and cranial nerves and is fatal by 2 years of age.
 - Type 3, the juvenile, neuronopathic subacute form, consists of involvement of visceral organs, bone, and the central nervous system, with neurologic symptoms appearing later and being less severe.

EPIDEMIOLOGY

Type 1 is the most common form of Gaucher disease (Table 207.1). Type 1 Gaucher disease (GD1) is more frequent in persons of Ashkenazi Jewish heritage but is pan-ethnic. Types 2 and 3 are rarer and affect predominantly non-Jewish individuals. A genetic isolate of type 3 has been identified in northern Sweden (so-called Norrbottnian Gaucher disease). No family has been reported with more than one type of the disease, thus suggesting that the three types of Gaucher disease are genetically distinct. Each type is inherited as an autosomal recessive trait without any sex preponderance. The peak age at onset is variable: any age from birth to elderly for type 1, usually before 6 months of age for type 2, and juvenile (teenage) for type 3.^{1,2}

An international registry database organized by the International Collaborative Gaucher Group has presently enrolled around 6000 patients worldwide.²⁻⁷ It provides a genotype reference resource and several clinical investigations on different aspects of the disease (e.g., evaluation of bone response by densitometry, dose schedule for enzyme replacement therapy, pulmonary involvement).

ETIOLOGY

Biochemistry

Gaucher disease arises from an inherited deficiency of the activity of acid β -glucosidase (EC.3.2.1.45; lysosomal glucocerebrosidase), a membrane-associated monomeric glycoprotein with a molecular weight of 65 kDa.^{1,2}

This enzyme hydrolyzes β -glucosidic ester bonds and is specialized for complex lipid substrates. Impairment of its activity results in the accumulation of glucosylceramide, linked by a β -glucosidic bond. Glucosylceramide is at the end of the glycosphingolipid catabolic pathway and is normally catabolized into ceramide and glucose by glucocerebrosidase.¹ The compounds that contribute to the pool of glucosylceramide are derived from the degradation of membranes, particularly those of white blood cells (Fig. 207.1).

Molecular biology and genetics

More than 300 discrete mutant alleles have been identified in the β -glucocerebrosidase gene (*GBA1*).² There is also a pseudogene that is about 96% homologous with the active gene and may complicate the pattern of mutations.² Mutations include both insertional and point mutations, as well as crossover mutations with the pseudogene. Four common mutations are found in 96% to 98% of the Ashkenazi Jewish population^{1,2}; the most common is an A→G point mutation at nucleotide 126, which results in substitution of serine for asparagine (370), decreased catalytic activity of the enzyme, and a mild phenotype. This mutant allele is not observed in patients with the neuronopathic type 2 or 3 forms. Other common mutations include (1) insertion of a guanine at nucleotide 84, which induces a shift in the reading frame with no enzyme production and a severe phenotype; (2) a T→C mutation at nucleotide 1448 in which proline is substituted for leucine (444), which causes severe loss of activity and a severe phenotype (homozygous patients have a neuronopathic form); and (3) a G→A mutation at nucleotide 1604, which results in substitution of histidine for arginine (496) and produces a very mild phenotype.¹

PATHOGENESIS

Physical crowding or impairment of blood flow secondary to the massive accumulation of storage cells has been hypothesized to explain some tissue alterations such as bone ischemia.¹ On the other hand, macrophage activation with alterations in macrophage function and the local release of lysosomal enzymes, chemokines, and cytokines may have deleterious effects on neighboring cells in the spleen, liver, bone, or central nervous system.²

However, these mechanisms do not explain the entire spectrum of the clinical phenotype in GD1, and recent observations in an animal model suggest an effect of *GBA1* deficiency on other cell types such as osteoblasts, thymic T cells, and dendritic cells.⁸ Conditional *GBA1* deletion in mice recapitulates most of the features of GD1 and shows that the skeletal abnormalities could result mainly from a defect in osteoblast differentiation and function. An imbalance in bone remodeling caused by decreased bone formation is also suggested in patients with GD1, as shown in a recent retrospective cohort study and review of the literature.⁹ A decreased osteocalcin level is present in about 50% of patients and correlates with the severity of bone involvement.

TABLE 207.1**Epidemiology of Gaucher disease type 1**

Peak age	Any age from birth to old age
Sex distribution	1 : 1
Prevalence rate (per 100,000), incidence, geography	15–40 in Ashkenazi Jews, rare (<1) in other populations; about 1 in 800 live births; panethnic
Genetic association	Association of sporadic Parkinson disease with heterozygous variants in the glucocerebrosidase gene
Transmission	Autosomal recessive

Fig. 207.1 The impaired activity of the lysosomal enzyme glucocerebrosidase results in the accumulation in macrophages of glucosylceramide, which is normally catabolized into ceramide and glucose.

CLINICAL FEATURES

GD1, the most common form of the disorder (Mendelian Inheritance in Man [MIM] No. 230800), is very heterogeneous as far as age at diagnosis and severity of clinical expression are concerned.

Hematologic manifestations and other extraskeletal disorders

The principal initial feature is splenomegaly, which is usually painless. Splenic rupture is rare, but infarction may occur, sometimes as the initial complaint. Primary hypersplenism with thrombocytopenia, anemia, and leukopenia occurs frequently. In most patients these abnormalities are not life-threatening and may go unrecognized for many years. Hepatomegaly is also common but occurs later in the course of the disease. A moderate increase in cholestatic enzymes is frequent; cytotoxicity, however, is rare but, when present, may be associated with the development of irreversible fibrosis. Liver failure has been reported in a few patients with portal hypertension and extensive fibrosis.

Several other extraskeletal disorders have been described in patients with GD1, especially pulmonary involvement in the form of interstitial lung disease or pulmonary vascular disease (severe pulmonary hypertension or hepatopulmonary syndrome). Several authors and a recent report from the Gaucher registry have mentioned an association of sporadic Parkinson disease with heterozygous variants of the glucocerebrosidase gene¹⁰ or with GD1. The relationship between GD1 and cancer was controversial for a long time, but a recent report showed that the number of cancers identified in patients in the international registry was comparable to that expected in the

Fig. 207.2 (a) Severe compression fracture of the T12 vertebra with subsequent hyperkyphosis. The T10 vertebra is also crushed and has a grade 2 fracture. (b) In the same patient, magnetic resonance imaging of the spine shows spinal cord compression and angulation, although the patient remained free of neurologic complications, and diffuse heterogeneous low-intensity signal of all vertebrae on this T1-weighted sequence.

reference population, except for multiple myeloma (estimated relative risk, 5.9; 95% confidence interval, 2.8 to 10.8).⁶ A 16% prevalence of monoclonal gammopathy in 107 patients was observed recently.¹¹

Bone involvement

Skeletal involvement, which is the major complication of GD1 that leads to pain and disability, affects 50% to 85% of patients with type 1, and up to 20% of patients have impaired mobility.^{12,13} Although it is the consequence of bone marrow infiltration, bone involvement correlates only poorly with visceral and hematologic disease.^{4,7} Even though bone features (in particular, avascular osteonecrosis [AVN]) have been found to be worsened after splenectomy in some studies, only anemia was associated with increased risk for AVN.^{7,14}

Before any treatment, 63% of patients complain of bone pain in the back, hips, legs, and shoulders.³ Osteopenia, present in 42% of cases,³ is characterized by decreased bone mineral density (BMD, as assessed by osteodensitometry)^{15,16} and thinning of the cortices. Fractures may occur, most frequently in the vertebral spine (36.4% of all fractures), followed by the lower extremities.⁷ Neurologic compression and thoracic hyperkyphosis have been reported as being consequences of severe or multiple vertebral fractures (Fig. 207.2).¹³ Low bone density in the lumbar spine were reported to be a strong risk factor for fractures of the spine and femur in a large retrospective study of 5894 patients from the International Collaborative Gaucher Group Registry.⁷

Failure of modeling during growth is the most characteristic skeletal abnormality.¹² It develops progressively throughout the period of rapid skeletal growth and is evident in about 80% of adults with the disease. Expansion of the contours of long tubular bones results in cortical thinning and loss of the normal concavity of the bony outline, particularly medially (Fig. 207-3). The so-called Erlenmeyer flask deformity is very suggestive of GD1, though not pathognomonic (see “Differential Diagnosis” and Box 207.1). Vertebral bodies sometimes show steplike depressions in the superior and inferior margins. This deformity, which has been termed *H vertebra*, is identical to that observed in sickle cell anemia.

Osteonecrosis and bony infarctions are the most common bone complications in GD1 and the most frequent cause of chronic pain and limitation of function. Both are the consequences of sudden ischemia in an infiltrated bone area and result in acute-onset episodes (bone crisis). All bones may be involved, including flat bones. Symptoms include acute pain, tenderness, and fever, similar to the symptoms of osteomyelitis or septic arthritis.¹²

Epiphyseal osteonecrosis frequently occurs at multiple sites and affects the femoral heads, humeral heads (see Fig. 207.4a and b), and less commonly, the femoral condyles and tibial plateaus. Radiographic changes are similar to those seen in other forms of osteonecrosis.¹² Secondary cartilage destruction often appears subsequently and results in a disabling arthropathy that may require total arthroplasty.¹² The typical radiographic appearance of bony infarctions consists of serpiginous osteosclerotic areas, which correspond to the calcified scar of the perimeter of ischemia, located nearby or within lytic lesions and associated with periostitis (see Fig. 207.4c). In the cortex, an inner layer of new bone formation that does not merge with the overlying cortical bone produces cortical splitting or a “bone-within-bone” appearance.

Fig. 207.3 Typical distal femoral deformity of the Erlenmeyer flask type on a radiograph of the distal end of the femur and proximal end of the tibia of a 31-year-old man. Note the expansion of the contour of the long tubular bones with convexity of the osseous margins, typical but not pathognomonic for Gaucher disease.

Increased susceptibility to bone infections has been reported. Septic arthritis is rare but osteomyelitis occurs in less than 5% of affected patients.¹⁵ The clinical features may simulate those of bone crisis. Bacteriologic findings, short-term repeated bone scintiscans, tomodensitometry, and magnetic resonance imaging (MRI) facilitate making the proper diagnosis.

BOX 207.1 DIFFERENTIAL DIAGNOSIS OF THE RADIOLOGIC FEATURES OF TYPE 1 GAUCHER DISEASE

Diffuse or localized osteopenia

Osteoporosis (idiopathic, corticosteroid induced)
Hyperparathyroidism
Hemoglobinopathies
Neoplastic disorders (multiple myeloma)

Osteosclerosis

Osteosclerotic skeletal metastasis
Phakomatosis (tuberous sclerosis)
Osteopetrosis
Mastocytosis
Osteomyelofibrosis
Hodgkin disease
Hemoglobinopathies

Osteonecrosis

Hemoglobinopathies (sickle cell anemia)
Hypercorticism
Caisson disease
Collagen vascular disorders
Hyperlipemia
Pancreatitis

Erlenmeyer flask deformity

Niemann-Pick disease
Pyle disease
Fibrous dysplasia
Hyperthyroidism
Hemolytic anemias (thalassemia)
Leukemia
Osteopetrosis (Albers-Schönberg disease)
Heavy metal poisoning
Rachitism sequelae
Fracture sequelae

Fig. 207.4 Typical features of ischemic bone complications in Gaucher disease. A standard radiograph (a) and T2-weighted magnetic resonance image (b) of the proximal end of the humerus show osteonecrosis of the left humeral head. (c) Radiograph of the right humeral diaphysis of a second patient shows bony infarction with heterogeneous condensation of the diaphyseal bone and a cortical reaction producing cortical splitting, the so-called bone-within-bone appearance.

INVESTIGATIONS

Biochemical studies

Current recommendations for the initial assessment of individuals with GD1 include confirmation of acid β -glucosidase deficiency and measurement of biochemical markers of the disease. Enzyme activity could be measured in circulating lymphocytes or on fibroblast cultures. Biochemical markers reflecting overloading of activated macrophages, such as plasma tartrate-resistant acid phosphatase, angiotensin-converting enzyme, ferritin, chitotriosidase, and more recently, chemokine CCL18/PARC, are useful for evaluating disease activity and monitoring response to therapy.^{2,17}

Imaging

Radiologic bone manifestations are found in more than 95% of patients, with features and frequency depending on the imaging method used.

Plain radiology makes it possible to view the basic lesions. As a result of infiltration of bone marrow by Gaucher cells, radiographs show increased radiolucency of bone and cortical scalloping and thinning. These abnormalities involve predominantly the axial skeleton and proximal long bones, where they are often symmetric. They are prominent in the distal portion of the femur and tibia (Fig. 207.5). In some cases they appear as limited massive osteolytic lesions in a metaphysis resembling a tumor or aneurysmal bone cyst and are called a “gaucheroma.”

The extent and severity of the disease vary and are poorly evaluated by radiography, computed tomography (CT), or bone scintigraphy. MRI has been shown to be the most sensitive technique for detecting early bone marrow changes and for assessing the extent and severity of marrow involvement.^{18,19} Many sites in the marrow are characterized by a signal of abnormally low intensity on both T1- and T2-weighted sequences (see Fig. 207-2b). The distribution of the abnormality is heterogeneous; vertebrae are consistently involved, but in the lower extremity the femoral areas are affected more frequently than the tibial sites. The epiphyses are generally spared unless the involvement of bone is extensive. Quantification of the infiltrate with scoring systems involving conventional MRI or experimental MRI techniques are now being developed.¹⁹ MRI allows early detection of ischemic bone lesions with a high-intensity signal on T1-weighted sequences at the time of clinical bone crisis. A decrease in BMD has been reported to correlate with the severity of skeletal involvement and may be useful for monitoring bone changes.¹⁵ Combining CT and technetium Tc99m

Fig. 207.5 Radiograph of the right tibial diaphysis of a 52-year-old man showing osteopenia, osteolytic lesions, cortical thinning, and scalloping.

methylene diphosphonate bone scintigraphy helps in the differential diagnosis between osteonecrosis and osteomyelitis in the clinical setting of sudden bone crisis. The presence of a necrotic soft tissue swelling adjacent to the affected bone is suggestive of an infectious complication. Increased uptake on a bone scintiscan performed a few days after the onset of a bone crisis suggests acute osteomyelitis, whereas its absence makes an ischemic bone crisis more likely.

Histology

Demonstration of Gaucher cells in bone marrow biopsy specimens is key to the diagnosis¹ but is not required in most patients when the clinical and biochemical features are characteristic. These large mononucleated or multinucleated cells have characteristic cytologic features with a typical “wrinkled tissue paper” appearance of the cytoplasm (Fig. 207.6). Bone tissue alterations are highly variable.

DIFFERENTIAL DIAGNOSIS

The bone features of GD1 are not specific and may be observed in other disorders (see Box 207.1), particularly the hemoglobinopathies (see Chapter 195). The diagnosis should be considered in a patient with hepatosplenomegaly who exhibits widespread osteopenia with a coarsened trabecular pattern, focal osteosclerosis, osteonecrosis of the proximal femoral epiphyses, and Erlenmeyer flask deformities of the distal portions of the femur.

MANAGEMENT

Current recommendations for the initial evaluation (Box 207.2) and monitoring of type 1 Gaucher disease in adult patients have been elaborated by the Gaucher registry coordinators.²⁰

Fig. 207.6 Light microscopy of Gaucher cells in bone marrow. Note the typical “wrinkled tissue paper” appearance of the cytoplasm (May-Grünwald-Giemsa stain; original magnification $\times 160$). (Prepared by Dr. Mallarmé.)

BOX 207.2 INITIAL ASSESSMENT OF PATIENTS WITH TYPE 1 GAUCHER DISEASE

1. History and pedigree
2. Comprehensive physical examination
3. Quality-of-life questionnaire
4. β -Glucocerebrosidase activity and genotyping
5. Primary blood tests: hemoglobin, platelet count
6. Biochemical markers of the disease: chitotriosidase, angiotensin-converting enzyme, TRAP
7. Additional blood tests: white blood cell count, hemostasis testing, serum immunoelectrophoresis, liver enzymes, calcium and phosphorus values
8. Assessment of visceral involvement: spleen and liver volume (MRI or CT)
9. Assessment of skeletal involvement:
 - a. Radiographs of the femora (posteroanterior view) and spine (lateral view)
 - b. MRI of the entire femora (coronal T1- and T2-weighted images)
 - c. Dual-energy x-ray absorptiometry of the lumbar spine and hip
10. Assessment of pulmonary involvement: electrocardiogram, chest radiograph, Doppler echocardiogram for measurement of right ventricular systolic pressure

CT, computed tomography; MRI, magnetic resonance imaging; TRAP, tartrate-resistant acid phosphatase.

Therapeutic goals

Following a consensus conference held in Amsterdam in October 2003, therapeutic goals have been proposed for each specific involvement of the disease.²¹ The following goals for skeletal involvement are recommended:

- Lessen or eliminate bone pain within 1 to 2 years.
- Prevent bone crises.
- Prevent osteonecrosis and subchondral joint collapse.
- Improve BMD—for pediatric patients, attain normal or ideal peak skeletal mass and increase cortical and trabecular BMD by year 2; for adult patients, increase trabecular BMD by 3 to 5 years.

Enzyme replacement therapy

Three forms of macrophage-targeted glucocerebrosidase are now available: recombinant glucocerebrosidase produced by DNA technology (imiglucerase [Cerezyme], Genzyme Corporation, Cambridge, Mass), human glucocerebrosidase produced in a human cell line with gene activation technology (velaglucerase alfa [VPRIV], Shire Human Genetic Therapies, Inc., Cambridge, Mass), and a carrot cell-expressed human recombinant β -glucocerebrosidase (taliglucerase alfa [Elelyso], Protalix Biotherapeutics, Carmiel, Israel). Glucocerebrosidase infusions reverse the hematologic complications and hepatosplenomegaly within 12 to 20 weeks,^{18,20,22,23} although bone response requires a longer period.²⁰ Bone pain and bone crises statistically decrease rapidly, with improvement at 3 months continuing progressively and the reduction being maintained for at least the first 3 years with a significant positive impact on quality of life.^{2,4,24-26} Risk for AVN is reduced in patients who initiated enzyme replacement therapy within 2 years of diagnosis.¹⁴ Imaging features improve after 1 to 2 years with an increase in BMD.^{4,15,22,25} Currently recommended therapeutic regimens start with 2-hour intravenous infusions of 60 IU/kg every 2 weeks.^{1,17} Even if there is a dose-response relationship for enzyme replacement therapy in GD1, optimal management is not well defined, and some patients experienced ongoing bone disease despite increased doses.^{2,27} Low-dose or intermittent-dosing regimens fail to achieve sustained improvement of the bone lesions or symptoms, and treatment for 2 to 3 years (lifelong in severely affected patients) is currently recommended. Because imiglucerase results in amelioration of osteopenia in all age groups, with the greatest improvements noted in younger patients, early treatment is recommended to attain better peak bone mass.¹⁶ MRI scores have recently been proposed for evaluating the therapeutic response.¹⁹ Chitotriosidase activity in serum is useful as an indicator of the efficacy of enzyme replacement therapy and as an early indicator of relapse after dose reduction or therapeutic interruption.²¹

Substrate reduction therapy

Miglustat is an iminosugar that decreases substrate synthesis. It has been shown to reduce hepatic and splenic volume and the incidence of bone pain

and to increase platelet counts.²⁸ It is approved by the U.S. Food and Drug Administration and European Medicines Agency for patients with mild to moderate GD1 who are intolerant of imiglucerase or unwilling to take enzyme replacement therapy. Eliglustat tartrate, an investigational substrate reduction drug and a specific inhibitor of glucosylceramide synthase, is currently in phase 3 trials.²⁹

Symptomatic treatments

Bone remodeling–targeted treatments and vitamin D

Antiresorptive therapy with high-dose alendronate in addition to enzyme replacement therapy increases BMD at 24 months without radiologic modification of focal lesions.³⁰ The effect on risk for fractures is unknown. The recent finding that osteoblast formation is impaired in patients with GD1 may suggest that bone anabolic agents could be explored as a treatment option. Because vitamin D deficiency seems to be frequent in patients with GD1, optimization of the vitamin D level is recommended.³¹

Splenectomy

Enzyme replacement therapy has considerably limited the indications for splenectomy because glucocerebrosidase infusions commonly reverse the hematologic disorders associated with hypersplenism¹⁷ and splenectomy has been shown to accelerate skeletal involvement.

Orthopedic treatments

Relief of bone and joint pain may necessitate the use of strong analgesics. Osteonecrosis or pathologic fractures often require surgery. Improved surgical techniques have increased the probability of good results and decreased the postoperative complications that were reported in historical series: bleeding, infection, and prosthetic loosening. For example, the first hip arthroplasty takes place at 43.8 years, 20 years earlier than in the general population and with as good results.^{32,33} Because of the frequency of atypical organisms, infectious complications (e.g., osteomyelitis) require both careful bacteriologic studies and prolonged antibiotic therapy.

Experimental therapies

Marrow transplantation has been shown to be curative in some patients, but the risks, which increase with the severity of the disease, do not justify this procedure in patients with relatively mild disease, especially since the development of enzyme replacement therapy.² An exception may be patients with neuronopathic disease. Somatic cell gene therapy is currently under investigation.

Management of Gaucher disease is a rapidly growing area. It now appears possible to prevent and reverse some of the most devastating and disabling complications of this disease, but initial evaluation plus monitoring of multiple compartments is necessary to better achieve more therapeutic goals. Prevention and treatment of bone complications will lead to much higher quality of life for all patients with GD1.

■ MARWAN A.S. BUKHARI

- Mucopolysaccharidoses are lysosomal storage diseases.
- The lysosomal defect is responsible for the deficient degradation of glycosaminoglycans.
- This complex group of mucopolysaccharidoses has several well-defined types; the most frequent forms are Hurler disease (type I) and Morquio disease (type IV).
- The main clinical features of the most common mucopolysaccharidosis (type I) are facial dysmorphism, visceral and corneal storage abnormalities, and skeletal disorders (dysostosis multiplex). Neurologic abnormalities are present in several types.

HISTORY

In 1917, Hunter¹ reported two brothers with coarse facies, mental retardation, and bone disorders. However, the first detailed description of mucopolysaccharidosis was by Gertrud Hurler² in 1919, who was inspired by Pfaundler. In 1929, Morquio and Brailsford gave a precise description of type IV mucopolysaccharidosis, and in 1963, Sanfilippo defined type III disease and Maroteaux and Lamy defined type VI disease.³⁻⁷

In 1952, Brante⁸ reported that the material stored in these patients was mucopolysaccharides. Dorfman and Lorincz documented increased urinary excretion of mucopolysaccharides, and Van Hoof and Hers demonstrated that mucopolysaccharides are stored in lysosomes.^{9,10} The corrective factors were then purified and their enzyme functions identified (Table 208.1). In 1962, Scheie and colleagues described a patient with corneal clouding, skeletal dysplasia, and coarsening of the features, and this was initially referred to as mucopolysaccharidosis V until it was discovered that it was a milder form of type I.^{11,12}

CLINICAL FEATURES

Type I

Hurler disease (mucopolysaccharidosis type IH) is the most typical of these disorders. It is usually apparent by 2 years of age and is characterized by facial dysmorphism, dorsal kyphosis, or mental retardation. The craniofacial morphology is typical, with macrocephaly, broad nasal bridge, full cheeks, thick lips, enlarged tongue, coarse hair, and hirsutism (Fig. 208.1). Joint movements are limited, and clawhand is common (Fig. 208.2). Lumbar kyphosis occurs frequently. The abdomen is protuberant, with hepatosplenomegaly and hernias. Corneal opacities are visible on slit-lamp examination. Cardiomyopathies have also been reported.¹³ Progressive mental and physical deterioration leads to death, often between 10 and 15 years of age.

Scheie disease (mucopolysaccharidosis type IS) is detected later, usually in childhood, and has a slow evolution.^{11,12} Joint stiffness, clawhand, heart murmurs, and corneal clouding are the main clinical manifestations of this form. Intermediate manifestations are frequently called Hurler/Scheie disease.¹⁴ Some of the milder forms of disease are usually detected only later in life because patients can have normal features and may report just Achilles tendon shortening or joint contracture.¹⁴

Radiographic features

Radiographs show macrocephaly, sagittal craniosynostosis, and an enlarged sella turcica. The ribs are wide, with an "oar-shaped" deformity. The

vertebral bodies are ovoid, and hooklike dysplasia is visible at the apex of the gibbus (Fig. 208.3). The midshafts of long bones are enlarged, with typical tilting of the distal ends of the radius and ulna toward each other, together with coxa valga. The epiphyses and carpal and tarsal bones are small and irregular. The iliac wing is small, and subluxation of the femoral head occurs frequently. The phalanges and metacarpal bones are shortened and enlarged, and the pointed proximal end of the metacarpals gives the characteristic "sugar loaf" appearance.¹⁵

Type II

Mucopolysaccharidosis type II is an X-linked recessive disorder. Its clinical and radiologic manifestations are similar to those of Hurler disease but are often more slowly progressive (Fig. 208.4), and the cornea is clear.

Type III

In mucopolysaccharidosis type III (Sanfilippo disease), the facial features and skeletal deformities are much milder than those in Hurler syndrome (Fig. 208.5). However, the mental and motor deterioration is precocious and severe.

Type IV

In type IV (Morquio disease), dwarfism is severe, with a short trunk, kyphosis at the thoracolumbar junction, pectus carinatum, and knock-knees (Fig. 208.6). Intelligence is normal, and no visceral storage is observed (only minimal corneal clouding). Universal platyspondyly with small odontoid processes, coxa valga, irregularities of the epiphyses and metaphyses, small and irregular carpal bones, and pointed proximal ends of the metacarpals are the more typical radiologic manifestations. The spinal cord compression secondary to atlantoaxial dislocation must be prevented by surgical intervention. Morquio type B syndrome is similar but has milder deformities.

Type VI

In type VI the facies is less grotesque than in Hurler disease. The cornea is cloudy, but mental development remains normal. Skeletal changes and dwarfism are variable but often severe.

Type VII

Mucopolysaccharidosis type VII (Sly disease) is very rare. It is associated with considerable phenotypic and bone deformity variations.¹⁶

HISTOLOGIC MANIFESTATIONS

In type I and type II disease, vacuolated lymphocytes are found with metachromatic inclusions in the vacuoles (Gasser cells). In addition, reticular cells of the bone marrow contain inclusions that vary from moderately coarse to very thick black-violet (type II Gasser cells).¹⁷ In type II, lymphocytes have also been described with pink-ringed vacuoles.¹⁸ In mucopolysaccharidosis type III, Gasser cells are more numerous, and plasmacyte cells containing vacuoles with metachromatic inclusions (Buhot cells) are found in the bone marrow. Alder anomaly is seen in type VI and is evident as coarse, dense granules in granulocytes, monocytes, and a large proportion of lymphocytes.

TABLE 208.1
Summary of the main types of mucopolysaccharidosis

	Skeletal dysplasia	Corneal opacities	Mental degradation	Inheritance	Urinary glycosaminoglycans	Enzymatic deficiency	Gene localization
Type IH (Hurler disease)	+	+	+	Autosomal recessive	Heparan sulfate Dermatan sulfate	α -L-Iduronidase	4p16.3
Type IS (Scheie disease)	$\pm$	+	–	Autosomal recessive	Heparan sulfate Dermatan sulfate	α -L-Iduronidase	4p16.3
Type II (Hunter disease)	–	+	$\pm$	X-linked recessive	Heparan sulfate Dermatan sulfate	Iduronidate-2-sulfate sulfatase	Xq27.3q28
Type III (Sanfilippo disease)	$\pm$	–	++	Autosomal recessive Autosomal recessive Autosomal recessive Autosomal recessive	Heparan sulfate	(a) Heparan sulfatase (b) <i>N</i> -acetyl-b-glucosaminidase (c) α -glucosaminide <i>N</i> -acetyltransferase (d) <i>N</i> -acetylglucosamine-6-sulfate sulfatase	17q25.3 17q21.1 14p13 12q14
Type IV (Morquio disease)	++ (a) + (b)	+	–	Autosomal recessive Autosomal recessive	Keratan sulfate	(a) <i>N</i> -acetylglucosamine-6-sulfate sulfatase (b) β -Galactosidase	16q24.3 3p21p33
Type VI (Maroteaux-Lamy)	+ / ++	+	–	Autosomal recessive	Dermatan sulfate	Arylsulfatase B	5p11p13
Type VII (Sly)	+	+	+	Autosomal recessive	Chondroitin sulfate	β -Glucuronidase	7q11.21q11.22

–, absent; $\pm$, could be present; +, mild; +/++, moderate; ++, severe.

Fig. 208.1 Hurler disease. Typical facial dysmorphism.

Fig. 208.3 Hurler disease. Note the hooklike deformity of the second lumbar vertebral body.

Fig. 208.2 Hurler disease. Clawhand is a common feature.

Fig. 208.4 Hunter disease. Note that the facial dysmorphism is milder than in Hurler disease.

Fig. 208.5 Sanfilippo disease. Mild coarsening of the facial features is apparent.

BIOCHEMICAL MANIFESTATIONS

Urinary elimination of dermatan sulfate and heparan sulfate is increased in type I and type II disease. Heparan sulfate is elevated in type III, keratan sulfate in type IV, and dermatan sulfate in type VI. These diseases arise from an inherited deficiency of the activity of lysosomal enzymes. For example, type I is characterized by an inherited deficiency of α -L-iduronidase (see Table 208.1).

Fig. 208.6 Morquio disease in a brother and sister. Note the short trunk with pectus carinatum and knock-knees.

PATHOGENESIS

The mucopolysaccharidoses are caused by a deficiency of specific lysosomal enzymes that catabolize glycosaminoglycans into shorter subunits for reuse or excretion. Deficiency of these enzymes results in intracellular accumulation and increased urinary excretion of the products of incomplete catabolism. As a result, cellular function is altered in cartilage, connective tissue, the heart, and the central nervous system.

The genes for these deficient enzymes have been mapped and cloned (see Table 208.1). Each gene has several mutations. The mutation 1113F is common and produces a severe phenotype, whereas the mutation T312S is found in patients with milder disease.¹⁹ However, significant interpopulation variation is observed.²⁰

MANAGEMENT

Management of all the mucopolysaccharidoses involves a multidisciplinary team approach that includes a neurologist; ear, nose, and throat and orthopedic surgeons; physiotherapists; and an experienced physician coordinating care.²¹ Advances have recently been made in disease-specific treatments, and these are summarized per disease and involve either enzyme replacement therapy (ERT) or hematopoietic stem cell transplantation (HSCT).

Mucopolysaccharidosis I: ERT for this disease is in the form of laronidase (0.58 mg/kg/wk). Laronidase is more effective in early disease.^{22,23}

HSCT for type I has been associated with a 3-year survival rate of 77%.²⁴

Mucopolysaccharidosis II: ERT for type II disease is in the form of idursulfase at a dose of 0.5 mg/kg/wk.²⁵ Trials of HSCT have been less successful.²⁶

The only other form of ERT to have been published is galsulfase for type VI.²⁷ HSCT has been used for the other diseases with variable results.²¹

New therapies are emerging, including a small-molecule approach, a gene therapy approach, and intrathecal drugs, all in early-phase experimentation.

Heritable connective tissue disorders

■ JOAN C. MARINI

OSTEOGENESIS IMPERFECTA

- Osteogenesis imperfecta is a genetic collagen-related syndrome characterized by abnormal bone matrix and secondary osteoporosis. Most cases (85%) are caused by autosomal dominant inheritance of defects in the genes coding for type I collagen, *COL1A1* or *COL1A2*, whereas rare recessive forms are caused by deficiency of proteins that interact with type I collagen posttranslationally for folding or modification, including the three components of the prolyl 3-hydroxylation complex (CRTAP, P3H1, CyPB) and two separate peptidyl-prolyl isomerases (HSP47 and FKBP10).
- Osteogenesis imperfecta is a generalized connective tissue disorder with variable nonosseous features, including abnormal scleral hue, hearing loss, dentinogenesis imperfecta, short stature, macrocephaly, joint laxity, and easy bruising.
- "Brittle bone disease" is susceptibility to fractures as a result of mild trauma.
- Forms of osteogenesis imperfecta range from those lethal in the perinatal period to those barely detectable.
- Treatment with bisphosphonates improves vertebral strength and geometry in children, but long-term detrimental effects on bone quality should limit use to 3 to 5 years.

EHLERS-DANLOS SYNDROME

- Ehlers-Danlos syndrome (EDS) is a genetic condition that affects joints, skin, and blood vessel walls.
- It is a heterogeneous group of generalized connective tissue disorders associated with multiple modes of inheritance and abnormalities of (predominantly) type III collagen in vascular EDS and type V collagen in hypermobility EDS, as well as some cases with defects in type I collagen and fibronectin, enzyme deficiencies, or abnormal copper metabolism.
- Joint involvement may include hyperextensibility of large or small joints and joint dislocations. Skin involvement may include a soft velvety texture, hyperextensibility, and fragility with stretched or "cigarette paper" scars.
- Vascular and visceral involvement ranges from easy bruising to life-threatening arterial rupture and rupture of the colon or uterus.

MARFAN SYNDROME

- Marfan syndrome is a genetic syndrome with abnormalities in the musculoskeletal, cardiovascular, and ocular systems.
- It is a generalized connective tissue disorder with variable clinical expression caused by defects in the fibrillin-1 gene, an extracellular matrix protein found in microfibrils. The overlapping conditions congenital contractural arachnodactyly and Loeys-Dietz syndrome are caused by defects in fibrillin-1 and subunits of the transforming growth factor- β receptor.
- Skeletal signs include tall stature, dolichostenomelia (long extremities), arachnodactyly, scoliosis, and chest deformities. Ocular signs include lens dislocation or subluxation.
- Cardiovascular manifestations include aortic root dilation and ascending aortic aneurysm. Treatment with β -blockers is the currently accepted standard; children who received the angiotensin receptor blocker losartan had a decreased rate of aortic root growth.

CHONDRODYSTROPHIES

- The chondrodystrophies are a large and strikingly heterogeneous group of heritable skeletal dysplasias with abnormal proportions of the limbs, trunk, and/or skull and often short stature.
- Disorders are classified according to the Paris nomenclature of 1976.
- Some chondrodystrophies have abnormal type II collagen. However, in most chondrodystrophies the abnormality in extracellular matrix is unknown.
- Skeletal involvement may include short or disproportionate stature and joint and skull abnormalities. Nonskeletal involvement may include abnormalities of the cardiac, ocular, or auditory systems.
- Achondroplasia, the most common chondrodystrophy, is evident at birth because of rhizomelic shortening of the limbs, large calvaria with a prominent forehead, trident hand, and lordosis.
- Stickler syndrome is characterized by ocular, facial, and joint involvement.

INTRODUCTION

In the past 20 years, dramatic progress has been made in understanding the molecular genetics of heritable connective tissue disorders. Various types of osteogenesis imperfecta (OI) have been shown to be caused by abnormalities in type I collagen or deficiency of proteins involved in collagen modification. Some types of Ehlers-Danlos syndrome (EDS) have been shown to be caused by abnormalities in types I, III, or V collagen. Some chondrodystrophies have been associated with abnormal type II collagen, whereas Marfan syndrome, long classified as a "collagen disorder," is caused by mutations in fibrillin-1 (*FBN1*), a component of the extracellular matrix.

These discoveries have served to highlight the basic principles that distinguish these disorders. First, they are primary connective tissue disorders with a primary heritable defect in a component of matrix. In contrast, the "collagen vascular" disorders exert their effect on connective tissue indirectly; a defect in one allele can inactivate 93% of the total product of both alleles. Second, metabolic disorders are usually symptomatic only when both alleles of a gene are defective. Third, connective tissue disorders display variability in the phenotype of individuals with the same mutation and genetic heterogeneity, because mutations in different genes can cause the same phenotype in different individuals.

OSTEOGENESIS IMPERFECTA**History**

The term *osteogenesis imperfecta* was first used by Vrolik in 1849. Since 1979, some form of the Sillence genetic classification has been in use.¹ In the early 1980s, Prockop demonstrated that OI was caused by abnormalities in type I collagen.^{2,3} Recently, discoveries have identified causes of recessive OI,³ namely, deficiency of proteins involved in collagen prolyl 3-hydroxylation or of two separate collagen peptidyl-prolyl *cis-trans* isomerases (PPIases) or deficiency of *SERPINF1/PEDE*. Dominant type V OI was shown to be caused by a single mutation in *IFITM5/BRIL*.

Epidemiology

The overall frequency of OI identifiable at birth is about 1 per 20,000 to 30,000.³ The frequency of mild type I OI has been estimated to be 1 in 30,000 in Australia.³ The overall prevalence and severity are not influenced by gender, race, or ethnic origin. However, a west African *LEPRE1* recessive founder mutation is carried by about 1.5% of contemporary Ghanians and Nigerians and also occurs in mid-Atlantic African Americans.⁴ Recessive OI accounts for 5% to 7% of OI cases overall.

Clinical features

Sillence classification

The modified Sillence classification of OI (Table 209.1)^{1,3} is based on genetic, clinical, and radiographic data. Type II OI is lethal in the perinatal period. The overwhelming majority of cases are associated with new dominant mutations; 10% of affected offspring of clinically normal parents are a result of germline mosaicism in one parent. Type III, the most severe form compatible with long-term survival, has a natural history characterized by extremely short stature, progressive scoliosis, and deformity of long bones. Type IV consists of moderately severe skeletal features with significantly short stature; this form is compatible with assisted ambulation. Individuals with type I OI have mild skeletal disease and frequently have blue sclerae.

The Sillence classification has been extended to types V to XI.³ Types V and VI were classified by their distinctive bone histology; their etiology has recently been identified as being due to a dominant mutation in *IFITM5* and recessive mutations in *SERPINF1*, respectively. Types VII, VIII, and IX have recessive inheritance. They are caused by null mutations in the genes encoding cartilage-associated protein (CRTAP), prolyl 3-hydroxylase-1 (P3H1), and cyclophilin B (CyPB),³ components of the collagen prolyl 3-hydroxylation complex. Types VII and VIII have a severe to lethal phenotype that clinically overlaps with that of types II and III and distinctive features, especially white sclerae. Types X and XI are recessive forms caused by deficiency of the collagen chaperone/PPIases HSP47 or FKBP10.³ The one patient with type X exhibited partial enzyme deficiency and early childhood demise, whereas FKBP10 deficiency causes a moderate to severe phenotype that incorporates congenital contracture disorders, Bruck syndrome, and Kuskokwim disease.³

Skeletal dysplasia

The skeletal system in OI is characterized by osteoporosis secondary to abnormal matrix, bowed long bones, compressed vertebrae, and triangular facies. Individuals with type II OI (Fig. 209.1a) have prenatal fractures of ribs and long bones and severe limb shortening and deformity. Relative macrocephaly, a soft membranous skull, and wormian bones are also features. Individuals with type III OI (see Fig. 209.1b) experience frequent fractures, progressive scoliosis, long-bone deformity, and metaphyseal flaring with “popcorn” formation. In type IV (see Fig. 209.1c and d) and type I, the long bones are generally well modeled, though relatively osteoporotic. Fractures usually occur after ambulation, are related to trauma, heal with minimal deformity, decrease dramatically in number after puberty, and recur after menopause.³ The skeletal dysplasia of recessive OI is extremely severe, with dual-energy x-ray absorptiometry (DEXA) z scores below –6 and the development of metaphyseal “popcorn” in midchildhood. Type V overlaps clinically with moderate OI but adds the triad of hypertrophic callus, ossification of the interosseous membrane, and dense metaphyseal bands, whereas patients with type VI have severe progressive deforming OI with wide osteoid seams and a slow mineralization time, as well as a “fish scale” pattern of lamellar bone under polarized light.³

Ocular features

Blue sclerae, caused by decreased scleral thickness, is common in classic dominant OI and occurs especially in types I and II. Some individuals with dominant OI have white sclerae. However, white sclerae in patients with severe or lethal OI are strongly associated with the recessive forms.

Dental features

Dentinogenesis imperfecta with grayish opalescent or brown-yellow dentition may be present and sometimes leads to crumbling of teeth. The permanent dentition is less severely affected.

Other systems

Hearing loss is a common feature of OI that occurs in about 50% of patients over their lifetime and is especially prevalent with type I.⁶ It is manifested as conductive or mixed hearing loss and develops in the early adult years. Pulmonary complications may be a significant source of morbidity and mortality.³ Infants with type II OI generally die of respiratory insufficiency.

TABLE 209.1
Modified Sillence classification of osteogenesis imperfecta

Type	Genetics	Description
I	Autosomal dominant	Mildest form of OI Mild to moderate bone fragility without deformity Associated with blue sclerae, early hearing loss, easy bruising May have mild to moderate short stature Type IA: dentinogenesis imperfecta absent Type IB: dentinogenesis imperfecta present Null mutations in <i>COL1A1</i>
II	Autosomal dominant	Perinatal lethal or recessive Extreme fragility of connective tissue, multiple <i>in-utero</i> fractures, usually intrauterine growth retardation Soft, large cranium Micromelia, long bones crumpled and bowed, ribs beaded Mutations in <i>COL1A1</i> or <i>COL1A2</i>
III	Autosomal dominant	Progressive deforming phenotype Severe fragility of bones, usually <i>in-utero</i> fractures Severe osteoporosis Relative macrocephaly with triangular facies Fractures heal with deformity and bowing Associated with white sclerae and extremely short stature, scoliosis Mutations in <i>COL1A1</i> or <i>COL1A2</i>
IV	Autosomal dominant	Skeletal fragility and osteoporosis more severe than in type I Associated with bowing of long bones; light sclerae with or without moderate short stature and moderate joint hyperextensibility Type IVA: dentinogenesis imperfecta absent Type IVB: dentinogenesis imperfecta present Mutations in <i>COL1A1</i> or <i>COL1A2</i>
V	Autosomal dominant	Moderate fragility Hypertrophic callus Dense metaphyseal bands Ossification of interosseous membranes “Meshlike” bone histology Mutation in <i>IFITM5</i> (BRIL)
VI	Autosomal recessive	Moderate to severe osteopenia secondary to a mineralization defect “Fish scale” lamellae on bone histology Mutations in <i>SERPINF1</i> (PEDF)
VII	Autosomal recessive	Perinatal lethality or severe dysplasia Caused by null (lethal) or hypomorphic (surviving) defects in CRTAP
VIII	Autosomal recessive	Perinatal lethality or severe bone dysplasia West African founder mutation, 1%-2% prevalence Caused by null mutations in <i>LEPRE1/P3H1</i>
IX	Autosomal recessive	Lethal to moderate Mutations in <i>PPIB</i> (CyPB)
X	Autosomal recessive	Severe deforming OI Blue sclerae and dentinogenesis imperfecta Mutation in <i>SERPINF1</i> (HSP47)
XI	Autosomal recessive	Moderate to severe deforming OI Variable congenital contractures (Bruck syndrome type I) White sclerae, normal teeth Mutations in <i>FKBP10</i> (FKBP65)

OI, osteogenesis imperfecta.
Data from Sillence DO, Senn A, Danks DM. Genetic heterogeneity in osteogenesis imperfecta. *J Med Genet* 1979;16:101-16; and Forlino A, Cabral WA, Barnes AM, Marini JC. New perspectives on osteogenesis imperfecta. *Nat Rev Endocrinol* 2011;7:540-57.

Fig. 209.1 Features of osteogenesis imperfecta. (a) Type II: short, crumpled long bones and rib fractures. (b) Type III: progressive deformity and osteoporosis of long bones. (c and d) Type IV: triangular facies, frontal bossing, shallow orbits, and long bones with moderate deformity and osteoporosis.

In types III and IV OI, pectoral deformities, scoliosis, and flaring and softness of the rib cage may predispose to frequent pneumonia or eventually cor pulmonale. Mitral valve prolapse may be present. Growth impairment³ affects virtually 100% of patients with types III and IV and is unrelated to fracture frequency or location. Patients with type I are shorter than their family members. Neurologically, children with types III and IV often have ventriculomegaly and sulcal prominence, even without macrocephaly. This does not indicate hydrocephalus and is not associated with intellectual impairment.

Investigations

The diagnosis of OI is usually apparent from the clinical and radiologic findings. The initial radiologic survey should also include lateral views of the skull and vertebrae. Normal or elevated serum alkaline phosphatase, calcium, and phosphate concentrations rule out metabolic mineralization disorders. In moderate and severe OI, periodic radiographs of the lower extremity long bones and vertebral bodies are useful for surgical and rehabilitative management. DEXA is useful for monitoring the progression of osteoporosis. Audiologic evaluation and pulmonary function tests every other year starting in childhood allow anticipatory management.

Prenatal detection of types II and III OI is possible with ultrasound. Analysis of collagen from chorionic villi has been accurate in detecting types II, III, and IV OI and allows diagnosis by 12 to 15 weeks' gestation.⁷ Cultured amniotic fluid cells may yield false-positive biochemical diagnoses.

Identification of the specific *COL1A1*, *COL1A2*, *CRTAP*, *LEPRE1/P3H1*, *PP1B/CyPB*, *IFITM5/BRIL*, *SERPINF1/PEDE*, *SERPINH1/HSP47*, or *FKBP10* mutation is useful for accurate genetic counseling and for establishing the diagnosis in ambiguous or mild cases. Biochemical analysis of fibroblast collagen is less sensitive for detection of mutations in the amino third of the α chains. It is most useful for detecting type I OI. Biochemical analysis

of collagen in recessive types VII, VIII, and IX OI shows full overmodification of collagen chains, as occurs with collagen mutations toward the COOH end of the helix.³ Direct sequencing at the DNA or complementary DNA (RNA) levels is more sensitive for the most common structural changes in collagen associated with types II, III, and IV OI. Overall, diagnostic tests demonstrate a type I collagen abnormality in about 85% of patients with OI. Recessive OI accounts for 5% to 7% of the total OI cases; the dominant type V OI may be as prevalent as 5% of OI cases in North Americans.

Etiology and pathogenesis

Structure and function

Dominant OI has been associated with defects in the structure or synthesis of type I collagen (Fig. 209.2).^{2,3,8} Type I collagen² is the major protein in human extracellular matrix and plays a crucial scaffolding role in bone, skin, ligaments, tendons, sclerae, and blood vessel walls. This wide distribution accounts for the generalized nature of OI.

Type I collagen is a heterotrimer composed of two $\alpha 1(I)$ chains and one $\alpha 2(I)$ chain twisted around each other in a right-handed helix. Each chain is synthesized as a propeptide with globular extensions at both ends and a central helical domain of 1014 amino acids. The helical domain is composed of repeating Gly-X-Y triplets, in which X and Y are often proline and hydroxyproline, respectively. Each exon begins with a glycine and ends with a Y codon.

The three chains of the helix initially associate through the globular carboxyl extension. Helix formation then proceeds linearly toward the N-terminus, with glycine residues occupying the core positions inside the helix. Concomitant with synthesis and helix formation, lysine residues are hydroxylated and glycosylated and proline residues are 4-hydroxylated. This modification occurs in multiple residues in the helical region; once the chains are in the triple-helical configuration, they are no longer accessible

Fig. 209.2 Organization of type I collagen genes and protein. Assembly of a heterotrimer containing a mutant chain, its effect on glycosylation, and cyanogen bromide mapping are shown.

to these modifying enzymes. Substitution of a charged or a polar amino acid for a glycine residue in one chain will result in a temporal delay in helix propagation. The portions of all three chains in the helix that are N-terminal to the substitution will then be exposed to the modifying enzymes for a longer period, and a greater proportion of potential sites will be glycosylated. Thus overmodification is a helical process and does not identify the mutant chain.

Some cases of recessive OI are caused by defects in a second collagen modification system.⁵ The prolyl 3-hydroxylation complex in the endoplasmic reticulum 3-hydroxylates a single residue (Pro986) on each $\alpha 1(I)$ chain. Deficiency of any of the components of this complex, CRTAP, P3H1, or CyPB, causes the severe or lethal recessive forms of OI.

Types X and XI OI are caused by defects in two collagen-related chaperones/PPIases, HSP47 and FKBP10.³ HSP47 is crucial for folding of the three α chains into a collagen monomer. FKBP10 deficiency does not have a significant effect on helix folding but instead affects hydroxylation of the collagen telopeptide lysine.

The terminal extensions of the procollagen helix are cleaved by specific peptidases in the extracellular space. The mature collagen molecules subsequently assemble into fibrils driven by hydrophobic and hydrostatic forces and are then stabilized by cross-link formation. Absent or diminished telopeptide hydroxylation in patients with FKBP10 deficiency is associated with a diminished ability to cross-link collagen into fibrils and results in sparse and disorganized matrix.³

Finally, types V and VI OI,³ for which the genes were identified only recently, appear to have their pathology at the level of matrix mineralization. PEDF, a potent antiangiogenic factor, is known to bind to collagen in matrix, and this interaction is crucial for its vascular effect. Investigation into the mechanisms of these types is just beginning.

Molecular defects and phenotypic correlations

The full range of OI phenotypes, from lethal to mild, is associated with defects in type I collagen. They can be broadly divided into quantitative and structural defects. Type I OI, the mildest form, is caused by quantitative defects⁹; that is, patients secrete about half the normal amount of type I collagen but their collagen is structurally normal. Usually, this is caused by nonsense or frameshift mutations in one allele of *COL1A1* that lead to premature chain termination.

Types II, III, and IV OI are caused by structural defects in either the $\alpha 1(I)$ or $\alpha 2(I)$ chains of type I collagen.⁸ Most (80% to 85%) of these structural defects consist of substitutions of another amino acid for one of the invariant glycine residues that occur in every third position along the chain. Fifteen percent to 20% of defects involve splice junctions. The genotype-phenotype relationships of mutations in the two α chains are complex. Mutations in the $\alpha 1(I)$ and $\alpha 2(I)$ chains are lethal in a third and a fifth of cases, respectively. No correlation has been found between the severity of bone dysplasia and the extent of collagen helix overmodification. Modeling of lethal and nonlethal mutations in the two chains reveals different correlations, thus supporting a distinct role for each chain in the extracellular matrix. Although most collagen mutations occur *de novo*, 5% to 7% of dominant cases are caused by parental germline mosaicism.³ This factor should be considered in genetic counseling and molecular testing.

Some patients previously classified as having type IV OI have been shown to have distinctive bone histology and were subsequently classified as having types V and VI OI. Type V OI is an autosomal dominant form characterized by hypertrophic callus formation, calcification of the interosseous membrane of the forearm, and a radiodense metaphyseal band.³ A mutation in *IFITM5/BRIL* in which five residues are added to the amino end of BRIL has been identified in type V OI, and this unique mutation appears to cause all cases of type V OI.¹⁰

Finally, recessive OI is genetically heterogeneous, with mutations in six different genes and more to come. In one group of recessive patients, OI is caused by deficiency of one of the posttranslational modification systems of collagen (see earlier). These patients have null mutations in *CRTAP*, *P3H1*, or *PPIB* and clinically have an extremely severe or lethal form of OI.⁵ Patients in whom recessive OI is suspected can be screened for gene expression by real-time polymerase chain reaction or sequencing. Risk for the recessive form is increased in African Americans who may have inherited a west African founder mutation. Type VI OI is caused by null mutations in *SERPINF1*, which causes nearly total absence of PEDF.³ Interestingly, absence of this antiangiogenic factor results in a mineralization defect with wide osteoid seams on bone histology and a prolonged mineralization lag time. Recessive types X and IX OI result from a deficiency of collagen chaperone/PPIases.³ For type X, only one proband has been described with deficiency of HSP47, not surprising given the importance of HSP47 in embryonic development. Type XI OI has an interesting phenotypic heterogeneity—the same mutations in *FKBP10* can also cause Bruck syndrome (OI with congenital contractures), even in siblings,³ thus showing that contractures are a variable manifestation of the mutation. An additional *FKBP10* mutation in which a single tyrosine residue is deleted causes a congenital contracture syndrome, Kuskokwim disease, which is associated with mild incidental skeletal findings in some patients.

Management Rehabilitation

The goal of physical rehabilitation in OI is to attain age-appropriate physical skills as a child and to retain them as adults. The specific goals range widely with age and severity and include independent or assisted ambulation, transfer ability, and wheelchair-assisted mobility.

Active physical therapy with a therapist experienced in OI should begin in infancy.¹¹ To prevent deformities and assist respiratory effort, severely

affected infants may require a custom-molded seating insert for proper positioning. Hydrotherapy¹¹ should begin in the bath in infancy and continue through life as swimming and water exercises. This improves general conditioning, as well as muscular strength for head and trunk control and independent extremity movements.

Children who are not expected to walk should be provided with a powered wheelchair for independent mobility in the preschool years. Children with ambulation potential should receive regular physical therapy to strengthen their abdominal, pelvic girdle, and lower extremity musculature and prevent contractures.¹¹ Some children may require surgical correction of lower limb deformities before weight bearing is attempted. When ready to pull to a standing position, they progress through ambulation aids such as walkers and crutches to independent ambulation.

Orthopedic management

An orthopedic surgeon experienced in treating OI is essential for a successful physical outcome. Even in severely affected individuals, fractures should not be allowed to heal without proper alignment and reduction. Fracture healing is generally normal in patients with OI; the period of immobilization should be minimized to avoid worsening osteoporosis secondary to disuse.

Intramedullary placement of rods in the long bones via the multiple osteotomy procedure of Sofield and Millar³ is used to interrupt refracture sequences, correct deformity, and support the bone for weight bearing. Extensible telescoping rods such as the Bailey-Dubow and, more recently, the Fassier-Duval models are used most often. They have the advantage of extending with bone growth. Unfortunately, however, they have a high rate of migration into a joint space. Furthermore, because the rod is much stiffer than normal bone, it bears a disproportionate share of the gravity load, which causes significant cortical atrophy. To circumvent the problems of rod migration and bone atrophy, a straight Sofield rod or a Rush rod with a crook may be used to stabilize a healing osteotomy in the lower limb. Generally, rods require replacement several times during childhood. The use of plates and screws to stabilize an osteotomy has resulted in increased osteoporosis of bone and poorly healed screw holes and cannot be recommended.

The scoliosis associated with moderate and severe OI is not responsive to Milwaukee bracing. When the scoliosis exceeds 40 degrees, spinal fusion with Harrington instrumentation generally provides good stabilization.

Management of generalized connective tissue symptoms

Bisphosphonate drugs have come into widespread use for OI based on observational trials. The consensus of three recent controlled trials involving children with OI¹² is that bisphosphonates are more beneficial for vertebrae than for long bones. Treatment for 1 to 2 years increases L1-L4 DEXA scores and, more importantly, improves vertebral compressions and area, which may prevent or delay the scoliosis of OI. The relative risk for long-bone fractures is somewhat decreased, in agreement with the increased load until fracture occurs in animal studies. However, such treatment weakens the material properties of long bones and increases the risk for osteotomy

nonunion. The consensus of the controlled trials is that bisphosphonate treatment does not affect muscle strength, ambulation status, or bone pain. Maximum benefit may be obtained with 2 to 3 years of treatment in mid-childhood; the benefits appear to persist for several years after treatment stops.

Growth deficiency is the most consistent secondary feature of OI. In a treatment trial of recombinant growth hormone for types III and IV OI in children,³ half the children (mostly with type IV OI) responded with more than a 50% increase in their linear growth rate, increased vertebral bone mineral density, and positive changes in bone histology.

Severely affected infants may have multiple bouts of pneumonia in the first years of life and should be treated promptly with antibiotics. To forestall the development of pulmonary hypertension and cor pulmonale, older patients with OI should be given oxygen when signs of desaturation appear.

The high-frequency hearing loss characteristic of OI can usually be overcome with amplification. If the conductive hearing loss is severe, stapedectomy can be performed but requires an OI-experienced surgical team to avoid fracturing the stapes or creating a "floating footplate."

EHLERS-DANLOS SYNDROME

History

Ehlers and Danlos each made a contribution to the associations of this syndrome shortly after 1900. Defects in types III, V, and I collagen, as well as in tenascin-X, lysyl hydroxylase, and the zinc transporter gene *SLC39A13*, have been identified in patients with EDS.^{13,14} The Villefranche nosology groups EDS into six types and eliminates rare forms.¹⁵

Epidemiology

The genetic inheritance and incidence of EDS vary widely with type.¹⁵ Fortunately, severe type IV EDS is rare and occurs in less than 1 in 100,000 births; the diagnosis is often made in childhood. Milder dominant forms of EDS are much more common, with an estimated prevalence of 1 in 20,000 for EDS type I.

Clinical features

The different types of EDS and their main clinical features¹⁵ are listed in Table 209.2.

Types I and II are the classic forms. Type I EDS is the gravis variant. Patients have velvety and hyperextensible skin, marked joint extensibility, "cigarette paper" scars, and easy bruisability (Fig. 209.3). Many are born prematurely or have mitral valve prolapse.

Type II EDS is a less severe manifestation of the type I clinical associations, except that premature degenerative arthritis may develop. In type III

Fig. 209.3 Features of Ehlers-Danlos syndrome. (a) Hyperextensibility of small joints. (b) Cigarette paper scarring. (Courtesy Dr. D. K. Grange.)

■ TABLE 209.2

Villefranche classification of Ehlers-Danlos syndrome

Former type	New classification	Genetics	Etiology	Clinical features
EDS I (gravis) EDS II (mitis)	Classic type	AD	90% of cases caused by mutations in <i>COL5A1</i> or <i>COL5A2</i>	Soft skin with scars Hypermobile joints Easy bruising Mitis less severe than gravis
EDS III	Hypermobility type	AD	Unknown	Soft skin without scars Marked mobility of large and small joints
EDS IV (arterial-ecchymotic)	Vascular type	AD	Defects in type III collagen	Translucent skin Marked bruising Ruptured arteries, uterus, bowel Normal joint mobility
EDS VI (ocular-scoliotic)	Kyphoscoliosis type	AR	Defects in lysyl hydroxylase	Skin soft and extensible Scoliosis Ocular fragility Hypermobile joints
EDS VIIA, VIIB (arthrochalasia multiplex congenita)	Arthrochalasia type	AD	$\alpha 1(I)$ $\Delta E6$ $\alpha 2(I)$ $\Delta E6$	Congenital hip dislocation Skin soft without scars Hypermobile joints
EDS VIIC (human dermatosparaxis)	Dermatosparaxis type	AR	Deficient procollagen N-proteinase	Congenital hip dislocation Skin soft without scars Hypermobile joints

AD, autosomal dominant; AR, autosomal recessive.
Data from Beighton P, De Paepe A, Steinmann B, et al. Ehlers-Danlos syndromes: revised nosology, Villefranche, 1997. *Am J Med Genet* 1998;77:31-7.

EDS, joints dislocate repeatedly and are associated with degenerative joint disease. Scars form normally.

Type IV EDS, the severest form, includes complications that reduce adult life expectancy (median survival, 48 years), such as rupture of arterial walls, colon, or pregnant uterus. Patients have a characteristic facies with large eyes and thin nose and lips, as well as marked bruisability, an aged skin appearance of the hands and feet, and small-joint hypermobility.

The arthrochalasia type of EDS is manifested predominantly as joint symptoms, beginning with congenital hip dislocations, usually bilateral, and continuing with striking joint laxity and multiple dislocations. Patients may have moderate short stature and dysmorphic cigarette paper scars.

Diagnostic studies

Biochemical and molecular studies of types V, III, and I collagen from fibroblasts are important to establish the genetics of EDS and to identify patients with type IV EDS for anticipatory management. Fibroblast lysyl hydroxylase deficiency and reduction of collagen cross-links in urine can be demonstrated in EDS type VI.¹⁶

Differential diagnosis

The features of EDS overlap with those of other connective tissue disorders, especially marfanoid hypermobility syndrome, cutis laxa, and mild OI. Neuromuscular disorders and Menkes syndrome are included in the differential diagnosis of some childhood EDS features.

Etiology and pathogenesis

Type III collagen

Type III collagen is a homotrimer encoded by a gene on chromosome 2q31. The $\alpha 1(III)$ chains have the Gly-X-Y repeats typical of fibrillar collagen. Type III collagen is located in skin, blood vessel walls, and pleuropertitoneal lining; bone has a minimal amount of type III collagen.

Molecular defects in types I, III, and V collagen

The most consistent molecular correlations in EDS have been type IV EDS with defects in type III collagen and type VII EDS with defects in type I collagen. Type IV EDS results from defects in the structure or synthesis of type III collagen. Some defects involve glycine substitutions or splice site defects. All cases are dominant heterozygous lesions, consistent with the fact that a mutation in one allele will result in 93% of homotrimers containing at least one mutant chain.

The arthrochalasia type of EDS involves defects in processing of the N-propeptide of type I collagen.¹⁷ The defective pN-collagen forms abnormal fibrils. Most cases are dominant structural defects involving skipping of exon 6 of type I collagen, which contains the N-proteinase cleavage site. More recently, the human equivalent of dermatosparaxis has been documented. This recessive form of EDS type VII is characterized by deficiency of the N-terminal proteinase.

Classic EDS (formerly types I and II EDS) involves defects in type V collagen, a quantitatively minor fibrillar collagen in skin, in more than 90% of patients.¹⁸ About half are null mutations in *COL5A1* that cause haploinsufficiency. The remainder are structural defects in *COL5A1* or *COL5A2* that result in reduced availability of type V collagen.

There is additional genetic heterogeneity in EDS. Defects in tenascin-X interfere in the deposition of collagen and elastin fibrils in dermis and cause a recessive form of classic EDS. Some cases of classic EDS are caused by defects in type I collagen, specifically, homozygous defects resulting in total absence of the $\alpha 2(I)$ collagen chain and heterozygous defects resulting in Arg-to-Cys substitutions in the helical region of $\alpha 1(I)$. Persons with classic OI caused by defects in type I collagen may also have a range of vascular problems.

Management

Sports that hyperextend or otherwise stress joints should be discouraged in childhood. Joint surgery may be performed for pain, instability, or poor range of motion. Success in terms of joint stability and relief of pain is limited in about half of cases.¹⁹ Joint effusions and hemarthrosis may occur as a result of cumulative minor trauma and require intervention to maintain ambulation.

The skin fragility in patients with EDS necessitates particular attention to closure after even minor surgical procedures. Sutures should be closely spaced and left in place for a longer period than normal.

Patients with a diagnosis of type IV EDS should communicate all vascular and visceral symptoms to their physician. The natural history of type IV EDS necessitates prompt evaluation of even vague complaints in pertinent systems, with echocardiography, computed tomography, or laparoscopy being performed as indicated.^{20,21} If pregnancy is attempted, elective cesarean section through the lower uterine segment is essential because the uterus will be stressed less than with spontaneous vaginal delivery and delivery-related tears can be prevented. The classic and hyperextensibility types of EDS are associated with premature rupture of membranes and preterm labor; obstetric management for determination of the delivery route and treatment of potential bleeding complications is considered on a case-by-case basis.¹³

MARFAN SYNDROME

History

This syndrome, initially reported by Marfan in 1896, was the first heritable disorder of connective tissue to be described. Marfan syndrome type 1 is caused by heterozygous mutations in *FBNI*, which encodes the matrix protein fibrillin-1. A mouse model that has been useful for translational studies was generated by Ramirez.²² Cumulative survival probability has increased from 48 years in 1972 to 72 years in 1995 because of surgical advances in prophylactic repair of the dilated aortic root, and survival has improved further by treatment with losartan.

Epidemiology

Marfan syndrome has an autosomal dominant inheritance and approximate prevalence of 1 in 5000 to 10,000.¹⁸ It is not associated with any racial or gender bias in prevalence.

Clinical features

Skeletal features

Musculoskeletal features,²² such as stature greater than the 95th percentile and limbs disproportionately long for trunk size (arachnodactyly), may first bring the patient to medical attention. Other skeletal aspects of Marfan syndrome include scoliosis, pectus excavatum (Fig. 209.4) or carinatum, and high-arched narrow palate, and laxity of joints, including flat feet.

Ocular features

Nonprogressive subluxation of the lens is present in about 60% of patients. It is most commonly bilateral, with the lens being displaced upward. Myopia is frequent and may be severe because of increased axial length of the globe.

Cardiovascular features

Mitral valve prolapse and dilation of the ascending aorta are the most common cardiovascular findings. Mitral or aortic regurgitation may develop. Histologically, the aorta demonstrates cystic medial necrosis. Dilation of the aortic root occurs in 60% to 80% of adults with Marfan syndrome, and ascending aortic aneurysms are the most common cause of morbidity and mortality.

Infantile Marfan syndrome

Marfan syndrome also has a severe perinatal subset. Progressive cardiovascular abnormalities and pulmonary disease cause increased morbidity and mortality in the childhood years.

Fig. 209.4 Marfan syndrome: pectus excavatum. (Courtesy Dr. K. Rosenbaum.)

Ghent nosology

The diagnostic criteria for Marfan syndrome were revised to include the diagnosis of Marfan syndrome in relatives of affected patients and the contribution of molecular diagnosis.²³ The Ghent nosology (Box 209.1) uses skeletal features as major criteria if at least four of eight typical skeletal features are present. A diagnosis of Marfan syndrome in the index case requires meeting the major criteria in at least two organ systems (skeletal, ocular, cardiovascular, skin, family history) and having involvement of a third system. Relatives of a confirmed case require major criteria in one system and involvement of a second system.

Prognosis

In the past, cardiovascular complications reduced the mean life span of patients with Marfan syndrome. With aggressive and anticipatory drug and surgical management of aortic root dilation, the majority of patients have a life span in the 50- to 70-year range.²⁴

Diagnostic studies

Studies essential for establishing a diagnosis of Marfan syndrome include a slit-lamp examination with fully dilated pupils and echocardiography focused on the mitral valve and aortic root. A radiographic skeletal survey should include the limbs, spine, skull, and chest. Detection of a fibrillin mutation contributes to the diagnosis, especially in children, but the diagnosis is primarily made clinically.

Differential diagnosis

Loeys-Dietz syndrome (LDS),²⁵ characterized by the triad of hypertelorism, cleft palate or bifid uvula, and aortic aneurysms or arterial tortuosity, is caused by mutations in *TGFBR1* and *TGFBR2*. LDS lacks ocular involvement. Homocystinuria has similar ocular and skeletal manifestations as Marfan syndrome but a positive urine cyanide nitroprusside test and downward lens dislocation. Congenital contractural arachnodactyly,²⁶ caused by mutations in *FBNI*, shares the Marfan skeletal traits. In “marfanoid” hypermobility syndrome, the lens and aorta are normal, and the skin and joints are more extensible than in Marfan syndrome. In vascular EDS, skeletal proportions are normal.

BOX 209.1 GHENT NOSOLOGY OF MARFAN SYNDROME

For an index case: diagnosis requires major criteria in at least two different organ systems and involvement of a third organ system.

For a relative of an index case: diagnosis requires a major criterion in one organ system and involvement of a second organ system.

Major criteria, skeletal system (4 or more):

- Pectus carinatum
- Pectus excavatum
- Span-to-height ratio >1.05
- Wrist and thumb signs
- Scoliosis >20 degrees
- Elbow extension <170 degrees
- Pes planus
- Protrusio acetabuli

Dura

- Lumbosacral dural ectasia evident on computed tomography or magnetic resonance imaging

Ocular system

- Ectopia lentis

Cardiovascular system

- Dilation of the ascending aorta involving at least the sinuses of Valsalva
- Dissection of the ascending aorta

Family/genetic history

- First-degree relative with Marfan syndrome
- Presence of an *FBNI* mutation

Etiology and pathogenesis

Classic Marfan syndrome is caused by mutations in fibrillin-1, a glycoprotein abundant in the aortic tunica media, ciliary zonules, periosteum, and skin. Mutation screening for the *FBN1* gene is available.²⁷ A genotype-phenotype comparison has been done in more than 1000 patients. *FBN1* mutations producing premature termination cause a more severe skeletal and skin phenotype than do in-frame mutations. Mutations causing severe neonatal Marfan syndrome or high cardiac risk usually occur in the epidermal growth factor–like sequences in exons 24 to 32, whereas mutations in the last seven exons are associated with milder phenotypes. Patients with a missense mutation producing cysteine have a higher probability of ectopia lentis. The pathophysiology of the disorder involves dysregulation of transforming growth factor- β signaling.

Management

Patients with Marfan syndrome are best managed at a tertiary center. Cardiovascular care includes annual echocardiography and electrocardiography until the aortic root exceeds 40 mm and more frequently thereafter. Prophylactic aortic surgery is usually performed when the aortic root diameter is about 50 mm. The Bentall procedure, which uses a composite graft to replace the aortic valve, root, and proximal ascending aorta, is associated with a survival rate higher than 90% but a lifelong need for anticoagulation.²⁴ In the early 1990s a valve-sparing approach was developed and achieved excellent results. Treatment with β -adrenergic blockers is standard preventive treatment, but their effect on aortic dilation or dissection is controversial.²⁸ The angiotensin II receptor blocker losartan restored the cardiovascular phenotype in the Marfan mouse model, and early results in children are encouraging.²⁹ A long-term losartan trial is ongoing through the National Heart, Lung and Blood Institute, as is a controlled combination trial of losartan and β -blockers (the Ghent Marfan Trial).³⁰ Risk for a catastrophic cardiovascular event during and after pregnancy is high, even for women with moderate aortic dilation. Management also includes annual ophthalmology and semiannual orthopedic evaluation. Because the deformity may recur, correction of pectus is best postponed until growth stops.

CHONDRODYSTROPHIES

The chondrodystrophies are classified according to the Paris nomenclature of 1976, which used clinical and radiographic criteria, such as different parts of the long bones involved (epiphyses, metaphyses, or diaphyses) and the presence of spinal involvement (Box 209.2).³¹ The genetic defects responsible for these conditions are wide ranging and include signaling defects and involvement of matrix structural proteins.³²

BOX 209.2 PARIS NOMENCLATURE OF CHONDRODYSTROPHIES

Osteochondrodysplasias

- I. Defects in the growth of tubular bones, the spine, or both
- II. Disorganized development of cartilage
- III. Abnormalities in the density of the cortical diaphyseal structure, metaphyseal modeling, or both

Dysostoses

- I. With cranial and facial involvement
- II. With predominantly axial involvement
- III. With predominant involvement of the extremities

Idiopathic osteolysis

Primary metabolic abnormalities

- I. Calcium, phosphorus, or both
- II. Complex carbohydrates
- III. Lipids
- IV. Nucleic acids
- V. Amino acids
- VI. Metals

From Rimoin DL, Lachman RS. The chondrodysplasias. In: Emery AE, Rimoin DL, editors. Principles and practice of medical genetics. Edinburgh: Churchill Livingstone; 1983, p. 703-735.

Stickler syndrome is characterized by ocular, facial, and joint involvement and commonly results from mutations that cause premature termination codons and haploinsufficiency in the gene that encodes type II collagen. About 25% of patients with Stickler syndrome have mutations in the genes encoding type XI collagen. Manifestations of the syndrome include myopia, retinal detachment, midface hypoplasia, midline clefting, and hearing loss, but their expression is highly variable. Progressive osteoarthritis of large joints may develop in the third or fourth decade.

History

Several studies have revealed the familial nature³² and the underlying molecular defects in this group of disorders. These advances have led to an attempt to classify the disorders (see Box 209.2).

Epidemiology

Achondroplasia, the most common chondrodystrophy, occurs in about 1 per 40,000 live births. McKusick-type metaphyseal dysplasia is relatively common in the Old Order Amish.

Hypermobility syndrome

■ RODNEY GRAHAME ■ ALAN J. HAKIM

- Joint hypermobility syndrome is now considered by most authorities to be a heritable disorder of connective tissue that is indistinguishable from, if not identical to, the hypermobility type of Ehlers-Danlos syndrome.
- Far from representing a mild (some say trivial) rheumatologic disorder occurring in healthy individuals, it is now seen as a multisystemic disorder of connective tissue that is responsible for chronic widespread pain (often mislabeled fibromyalgia), gastrointestinal dysmotility, anxiety and phobic states, and dysautonomias, thus adding additional tiers of symptoms to the already wide panoply of the musculoskeletal sequelae of joint pain and instability and a predisposition to soft tissue trauma.
- Effective treatment is now available and consists of physical rehabilitation adapted to the needs of patients with lax and fragile tissues combined with effective pain management such as cognitive-behavioral therapy. Analgesics are often ineffective.
- Failure to institute effective treatment leads to progressive loss of function, self-efficacy, and quality of life. Untreated patients become physically disabled—some immobile, dependent, depressed, and desperate. Joint hypermobility syndrome is frequently overlooked and misdiagnosed and is the cause of much needless suffering.

INTRODUCTION

Hypermobility denotes an increased range of joint movement. Joint mobility is pronounced at birth but declines thereafter. It is greater in females and people of Asian or African descent. Hypermobility syndrome, also now known as (benign) joint hypermobility syndrome (JHS), is a common disorder. Originally defined as “the occurrence of symptoms in otherwise healthy hypermobile individuals,”¹ it is now seen as a complex genetic disorder with manifestations that permeate well beyond the confines of the musculoskeletal system. Most authorities regard it as being the same as the hypermobility type of Ehlers-Danlos syndrome (EDS-HT), formerly EDS type III (see Chapter 210).²

MOLECULAR BASIS, HERITABILITY, PATHOGENESIS, AND EPIDEMIOLOGY

Hypermobility is strongly “heritable”; one twin study showed 70% of its variance to be accounted for by genetic factors.³ Racial differences in prevalence also implicate genetic influences. Asian and Afro-Caribbean populations have a higher prevalence of hypermobility than whites do. The heritability of JHS has not been determined; however, anecdotal observations suggest dominant inheritance with variable penetrance. Both hypermobility and JHS are three times more common in females than in males. Hormonal influences may play a role, although the mechanisms have not been identified. Anecdotally, individuals with JHS observe that their symptoms are often worse immediately before menstruation, a point when serum estrogen levels peak in the cycle.

Collagen is abundant in virtually all connective tissue. Ultrastructural abnormalities in collagen fibrils and mutations in collagen-modifying enzymes have been found in all subtypes of EDS with the exception of EDS-HT. Like EDS-HT, mutations involved in the pathology of JHS remain obscure. Linkage analysis in two large families with JHS failed to show any

association with *COL1*, *COL3*, *COL5*, or *COL6* as causative genes.⁴ Other candidate genes for proteins involved in collagen fibrillogenesis, in particular, the family of small leucine-rich proteoglycans (SLRPs), have also not shown associations. Of note, deficiency in tenascin-X, an extracellular matrix glycoprotein, results in a phenotype similar to that of classic EDS. Haplo-insufficiency of the gene for tenascin-X has been found to account for some of the disorder's presence in families with EDS-HT and may in part explain the nature of the molecular disturbance in JHS.⁵

The epidemiology of JHS is in its infancy. However, surveys conducted in the United Kingdom and Chile suggest that the JHS phenotype may be identifiable in more than 40% of patients attending routine community hospital rheumatology clinics.⁶

RECOGNITION, DIFFERENTIAL DIAGNOSIS, DIAGNOSTIC CRITERIA

Various scoring systems for hypermobility have been devised. The most widely used is the 9-point Beighton scale (Table 210.1).⁷ Introduced in 1973, it has stood the test of time. However, it is an “all or none” criterion that gives no indication of severity. Because only five body sites are sampled, hypermobility may be missed, especially the pauciarticular variety. Hypermobility may be uncovered by a person's response to a validated 5-point questionnaire. Two affirmative answers would suggest an 85% chance of being hypermobile (Box 210.1).⁸ Hypermobility syndrome is diagnosed with the 1998 “Brighton criteria,”⁹ in which relevant symptoms, a low Beighton score, and other phenotypic features are included (Box 210.2).

Patients with JHS also often display increased skin stretchiness, a marfanoid habitus (complete or incomplete), and other manifestations that overlap with other heritable disorders of connective tissue. Rheumatologists need to be aware of the distinctive features of true Marfan syndrome and the other major forms of EDS, notably the classic form (EDS type I/II) and the life-threatening vascular form (EDS type IV), and be ever vigilant of their possible appearance. In this regard, the Ghent¹⁰ and Villefranche¹¹ criteria for Marfan syndrome and EDS, respectively, are essential reading.

CLINICAL FEATURES

Musculoskeletal

Once perceived as a trivial ailment causing minor joint and spinal pain after exercise with the occasional occurrence of joint dislocation predisposing in some cases to premature osteoarthritis, it is now regarded as a *forme fruste* of heritable disorders of connective tissue with features overlapping other types of such disorders. In practice, JHS may be manifested as (1) almost any soft tissue injury or overuse lesion affecting a ligament, tendon, muscle, enthesis, or joint; (2) recurrent joint instability, subluxation, or dislocation; (3) chronic noninflammatory joint or spinal pain without apparent structural abnormality; and (4) secondary osteoarthritic or spondylotic changes in peripheral or spinal joints, respectively. What sets patients with JHS apart from others is the range and frequency of the manifold varieties of acute and chronic painful episodes occurring over the course of their lives, with the intensity of pain seemingly increasing inexorably over time from childhood to adolescence and through adult life. Avoidance of (painful) movement as a strategy to avoid pain (described as kinesiphobia) inevitably leads to muscle deconditioning, the development of adverse postures, and loss of function, which serve only to aggravate a fraught situation and diminish the ability to lead a normal active life with a reasonable quality of life.

TABLE 210.1
Nine-point Beighton hypermobility score

Ability to	Right	Left
1. Passively dorsiflex the fifth metacarpophalangeal joint to $\geq 90^\circ$	1	1
2. Oppose the thumb to the volar aspect of the ipsilateral forearm	1	1
3. Hyperextend the elbow to $\geq 10^\circ$	1	1
4. Hyperextend the knee to $\geq 10^\circ$	1	1
5. Place the hands flat on the floor without bending the knees	1	
Total	9	

One point may be gained for each side for maneuvers 1 to 4 such that the hypermobility score will have a maximum of 9 points if all are positive.
 From Beighton PH, Solomon L, Sankolne CL. Articular mobility in an African population. *Ann Rheum Dis* 1973;32:413-7.

BOX 210.1 FIVE-PART QUESTIONNAIRE FOR IDENTIFYING HYPERMOBILITY

- Can you now (or could you ever) place your hands flat on the floor without bending your knees?
- Can you now (or could you ever) bend your thumb to touch your forearm?
- As a child did you amuse your friends by contorting your body into strange shapes or could you do the splits?
- As a child or teenager did your shoulder or kneecap dislocate on more than one occasion?
- Do you consider yourself double-jointed?

Affirmative answers to two or more questions suggest hypermobility with a sensitivity of 80% to 85% and a specificity of 80% to 90%.
 From Hakim AJ, Grahame R. A simple questionnaire to detect hypermobility: an adjunct to the assessment of patients with diffuse musculoskeletal pain. *Int J Clin Pract* 2003;57:163-6.

BOX 210.2 1998 BRIGHTON REVISED DIAGNOSTIC CRITERIA FOR BENIGN JOINT HYPERMOBILITY SYNDROME

Major criteria

1. A Beighton score of 4 of 9 or greater (either currently or historically)
2. Arthralgia for longer than 3 months in four or more joints

Minor criteria

1. A Beighton score of 1, 2, or 3 of 9 (0, 1, 2, or 3 if older than 50 years)
2. Arthralgia in one to three joints or back pain, spondylosis, or spondylolysis/spondylolisthesis
2. Dislocation in more than one joint or in one joint on more than one occasion
3. Three or more soft tissue lesions (e.g., epicondylitis, tenosynovitis, bursitis)
4. Marfanoid habitus (tall, slim, span greater than height; upper segment–lower segment ratio <0.89 , arachnodactyly)
5. Skin striae, hyperextensibility, thin skin, or abnormal scarring
6. Eye signs: drooping eyelids, myopia, or antimongoloid slant
7. Varicose veins, hernia, or uterine/rectal prolapse

Benign joint hypermobility syndrome (BJHS) is diagnosed in patients with two major criteria, one major and two minor criteria, or four minor criteria. Two minor criteria will suffice in those with an unequivocally affected first-degree relative. BJHS is excluded by the presence of Marfan syndrome or Ehlers-Danlos syndrome (other than the hypermobility type of Ehlers-Danlos syndrome [EDS], formerly EDS III), as defined by the Ghent 1996¹⁰ and Villefranche 1998¹¹ criteria, respectively. Major and minor criteria 1 and 2 are mutually exclusive.
 From Grahame R, Bird HA, Child A, et al. The revised (Brighton 1998) criteria for the diagnosis of benign joint hypermobility syndrome (BJHS). *J Rheumatol* 2000;27:1777-9.

Extraarticular manifestations

Mechanical failure of connective tissue beyond the locomotor system will be expected to be evident clinically. The dermis of the skin, being 70% collagen by dry weight, is abnormal in JHS. Its texture is soft or silky, its thickness is palpably reduced, it may be visibly transparent, and skin stretching is increased. Scar formation is impaired, which gives rise to characteristically

paper-thin scars. Stretch marks (striae atrophicae) as a result of internal slippage of dermal collagen bundles usually appear around the time of puberty, and by contrast, striae gravidarum are often paradoxically absent (Fig. 210.1).

Visceral complications arise from weakness affecting supporting structures such as the diaphragm, abdominal wall, and pelvic floor. Thus, hiatal hernias (with the closely associated gastroesophageal reflux) and abdominal wall hernias occur. In later life, uterine or rectal prolapse, rectocele, or cystocele (with or without stress incontinence) may develop in parous women with JHS. Varicose veins are also a common occurrence in JHS. Mitral valve prolapse and spontaneous pneumothorax are rarer manifestations.

Depression and anxiety are frequent accompaniments of the chronic pain in JHS, but the connection may be more fundamental. A link between hypermobility and panic attacks and phobias secondary to a chromosomal duplication has been postulated but thus far unconfirmed.¹²

Pain, fatigue, and dysautonomia

Pain, fatigue, depression, and anxiety are common in JHS. Pain is both acute and chronic. The chronic pain of JHS is best likened to that seen in patients with widespread chronic pain syndrome or fibromyalgia. Fatigue is often a severely disabling complaint, but its cause remains elusive.

Perhaps most surprising is the recent observation that up to 60% of patients with JHS have symptoms suggestive of an autonomic disturbance, including presyncope, syncope, and palpitations as a consequence of orthostatic hypotension, orthostatic intolerance, and postural orthostatic tachycardia syndrome. Bowel disturbance akin to irritable bowel syndrome is also reported.^{13,14} Vascular disturbance may be related to the increased reactivity of α - and β -adrenoreceptors in the vasculature and vagal hyperactivity.¹³ Recent studies have shown a significant association between JHS and the occurrence of gastrointestinal symptoms such as bloating, reflux, constipation, and diarrhea. Functional studies on individual patients reveal pan-intestinal dysmotility, which may result from laxity of intestinal connective tissue.¹⁵

The combination of all these symptoms is encountered commonly in the clinic. It is likely that their interactions are linked in a complex manner, each potentially “fueling” the other, as is depicted in Figure 210.2. Here, injury can lead to pain and maladaptive function, both physical and psychological. Likewise, primary psychological triggers may lead to anxiety and fatigue. Both these phenomena interact with each other and may also account for the secondary autonomic symptoms. In patients with a primary autonomic disturbance, the scene is set for a cycle of insults, each driving other components in the pyramid.¹⁶

MULTIDISCIPLINARY MANAGEMENT

Drug treatment

Simple analgesics and antiinflammatory drugs have an important place in the management of acute and acute-on-chronic pain from soft tissue injuries and degenerative disease, as with any other condition. The majority of patients, however, report that these agents are of little benefit in the control of chronic pain.

Local injection of corticosteroid may also be of value in treating isolated soft tissue lesions. Theoretically, despite the lack of an evidence base to favor or refute it, the risk for tendon rupture may be greater in patients with JHS than in the general population. Corticosteroid inhibits fibroblast formation, and this may add to the risk for delayed or poor healing of soft tissue already inherent in JHS.¹⁷ The clinician should also be aware of the poor efficacy of local anesthetics. Up to 60% of patients with JHS report failure or the need for additional local anesthetic. The mechanisms behind this are unclear.¹⁸

Patients with JHS are similar to those with fibromyalgia and widespread chronic pain with respect to the phenomenon of chronic pain amplification in the absence of chronic tissue injury. Serotonergic and noradrenergic agents can be used in this context, although no randomized controlled trials of the use of these agents for JHS have been conducted. It is speculative how much such agents influence central pain processing, mood, and consequent behavior and how much they influence stimulation of the spinal column descending inhibitory pain pathways. Similarly, such agents may have a place in patients with JHS in controlling autonomic disturbances of the bowel.

β -Blockade may relieve the symptoms of postural orthostatic tachycardia syndrome. Nonpharmacologic interventions such as attention to salt and fluid balance are likely to be most effective in managing orthostatic hypertension and orthostatic intolerance in these patients.

Fig. 210.1 (a and b) Skin stretching in an individual with joint hypermobility syndrome (JHS). (c) Papyraceous scar after a patellar tendon operation. (d) Lumbar region of a patient with JHS showing the characteristic striae atrophicae together with a papyraceous scar from spinal surgery.

THE POTENTIAL ASSOCIATION BETWEEN HYPERMOBILITY, ANXIETY, FATIGUE, CHRONIC WIDESPREAD PAIN, AND AUTONOMIC DYSFUNCTION

Fig. 210.2 Primary autonomic disturbance may add to anxiety and fatigue. Secondary autonomic disturbance may be a consequence of anxiety driven by pain and disability. (Reproduced by kind permission of the publishers of *Best Practice & Research. Clinical Rheumatology*.)

New physiotherapeutic approaches

Conventional physiotherapy has often been deemed unhelpful (or counterproductive) by patients with JHS. However, a new approach has been developed in which physiotherapeutic methods are adapted to the needs of patients with lax tissues who lack the normal tensile strength by

- Seeking to build up the muscles responsible for joint and core stability
- Restoring diminished proprioceptive acuity, with several studies showing that proprioception is impaired in hypermobile joints and can be improved by exercise and training¹⁹
- Avoiding harmful postures (e.g., resting at the end of the hypermobile range)
- Applying mobilizing techniques to restore to the natural hypermobile range those areas (e.g., the dorsal spine) that tend to stiffen up to the detriment of the non-stiffened hypermobile segments²⁰
- Working with clinical psychologists to enable patients with chronic pain to acquire pain management techniques such as pacing, relaxation, and so on
- Educating patients about JHS and encouraging self-management

Occupational therapy and podiatry

Occupational therapists provide splints to protect unstable finger joints and advice on joint protection in general. Specific devices (e.g., fat pen handles) can be an invaluable aid in writing.

Flatfoot on weight bearing (which disappears when not weight bearing) is a common finding in JHS, as is forefoot pronation and hindfoot valgus deformity. These deformities can produce discomfort and difficulty walking. A podiatrist can provide molded orthoses (insoles) capable of relieving such symptoms in patients with JHS.

Self-management

The nature and impact of JHS are not well appreciated by the medical community at large, and for this reason patients often remain undiagnosed and untreated for years and are forced to rely, to a large extent, on their own devices. It is not surprising that patient self-help groups have been formed and run by people who are also sufferers. In the United Kingdom, self-help groups play an important role in providing information and support for their

members by distributing leaflets, books, and newsletters; holding study days; and maintaining interactive websites. In the United Kingdom, active groups include the Hypermobility Syndrome Association, the Ehlers-Danlos Support Group, and the Marfan Association. Details are available through the Internet.

FUTURE TRENDS IN RESEARCH

Much remains to be understood about this common and debilitating condition. Identification of causative genes will lead to greater understanding of

the pathogenesis of the condition. Neurophysiologic mechanisms leading to impaired proprioception, autonomic disturbance, local anesthetic failure, and pain amplification also warrant further investigation.

At a therapeutic level, randomized controlled trials of pharmacologic, physical, and psychology techniques are lacking. Before such trials can be conducted, however, good objective, subjective, and patient-centered outcome measures need to be identified.

Skeletal dysplasias

■ CLAIR A. FRANCOMANO

- Skeletal dysplasias are a heterogeneous group of inherited disorders associated with structural abnormalities of the skeletal system. They can affect the bones of the spine, as well as those of the appendicular skeleton; most patients have short stature.
- Skeletal dysplasias are classified on the basis of clinical, radiographic, and molecular features.
- Achondroplasia, the most common skeletal dysplasia, is caused by a mutation in the gene encoding fibroblast growth factor receptor 3.
- Medical management is largely symptomatic.
- Surgical management has significantly improved functional ability and quality of life in patients with skeletal dysplasias.

INTRODUCTION

The term *skeletal dysplasias* refers to a clinically and molecularly heterogeneous group of inherited disorders primarily associated with structural anomalies of the skeletal system. More than 450 developmental disorders of the skeletal system have been described.¹ If one includes the broader spectrum of disorders in which multisystem abnormalities are present, including bone, joint, and limb malformations, more than 500 distinct syndromes are known.² This chapter presents an overview of the skeletal dysplasias, including molecular abnormalities, their translation into skeletal structural abnormalities, the role of imaging in defining the syndromes and assessing clinically significant deformities, and discussion of specific syndromes that have a high incidence of rheumatologic sequelae.

The skeletal dysplasias have a high frequency of rheumatologic complications involving both the axial and appendicular skeleton. Patients with disorders characterized by angular deformities of the long bones, joint surface irregularities, joint contractures, and joint instability are at particularly high risk for rheumatologic complications. Patients with disorders characterized by structural anomalies of articular cartilage are at high risk for the development of secondary osteoarthritis.

CLASSIFICATION

Skeletal dysplasias have been recognized since antiquity, primarily because many are associated with profound short stature. Efforts at categorizing these conditions began in the mid-20th century. Classification criteria have been based on clinical, radiographic, and molecular approaches. Early clinical distinctions were made between “short-limbed” dwarfism and “short-trunk” dwarfism. Radiographic classification has centered on the anatomic location of the radiographic anomalies, for example, epiphyseal, metaphyseal, diaphyseal, or in the spine. A number of disorders are defined by these localized affected regions, such as multiple epiphyseal dysplasia, the Schmid type of metaphyseal dysplasia, and Camurati-Engelmann diaphyseal dysplasia.

Recent advances in identifying the molecular pathogenesis of the skeletal dysplasias have led to a molecular classification of these disorders.^{1,3} Increasingly, the skeletal dysplasias are defined molecularly, according to the relevant molecular pathway.

MOLECULAR ASPECTS OF LIMB MORPHOGENESIS

The characteristic histologic appearance of the developing limb from the limb bud stage to skeletal maturation has been known for more than a century. Increasing knowledge of the timing and anatomy of gene expression in long-bone, epiphyseal, and joint development has resulted in a deeper understanding of the molecular events driving the complex processes involved.

Molecular analysis of the skeletal dysplasias has taught us much about the role of specific genes in skeletal development. The most recently published international nosology and classification of constitutional disorders of bone describes 456 conditions placed into 40 groups defined by molecular, biochemical, or radiographic criteria (or any combination of these criteria).¹ Box 211.1 outlines some of the mutations detected in skeletal dysplasia syndromes. New information is accumulating rapidly.^{4,5} Many aspects of craniofacial, axial, and appendicular skeletal growth and development can now be correlated with expression of genes encoding specific molecules such as growth factors and structural proteins. The complex process of bone growth at the epiphyses has been dissected at the molecular level. Multiple different molecular abnormalities can lead to disruptive effects on the timing of development and shape of the epiphyses and thereby result in angular deformity and joint incongruity. Other mutations affect the structural integrity of the articular cartilage and lead to increased risk for early osteoarthritis.

HISTOPATHOLOGY

Histopathologic analysis of the skeletal dysplasias is challenging because of the difficulties inherent in sectioning and staining cartilage and calcified bone. As a result, pathologic analysis has not played a prominent role in classification and clinical diagnosis of the skeletal dysplasias. Nonetheless, many studies show specific chondrocyte and matrix pathology in animal models and human tissue from patients with a variety of skeletal dysplasias.

At the ultrastructural level, changes in chondrocyte endoplasmic reticulum include massive dilation with retention of electron-dense homogeneous material (as in osteogenesis imperfecta and spondyloepiphyseal dysplasia), alternating electron-dense and electron-lucent whorled lamellae (as in pseudoachondroplasia),⁶ and alternating electron-dense and electron-lucent parallel lamellae (as in multiple epiphyseal dysplasia) (Fig. 211.1).⁷ These changes are reflective of abnormal intracellular protein processing. Matrix studies have shown early abnormal aggregation of type II collagen fibrils within the cartilage matrix in diastrophic dysplasia (Fig. 211.2).⁸ An overview of these features has been presented elsewhere.⁹

IMAGING

All the most frequently used imaging modalities currently available play a major role in assessment of patients with a skeletal dysplasia.

Ultrasonography

Ultrasonography is particularly valuable for intrauterine assessment in the fetal period.¹⁰ Fetal ultrasound evaluation may identify angular deformity or

 - Hereditary multiple exostoses

See [reference 1](#) for a full list of 456 recognized genetic skeletal disorders and their grouping by clinical and radiographic features and molecular pathogenesis.

Fig. 211.1 An electron micrograph of an iliac crest chondrocyte from a biopsy specimen from a 10-year-old boy with multiple epiphyseal dysplasia shows dilated rough endoplasmic reticulum (arrow) containing parallel lamellae of alternating electron-dense and electron-lucent material. Also note the pathologic presence of a circular fat inclusion. Studies identified a mutation in the $\alpha 3$ chain of type IX collagen. The material in the rough endoplasmic reticulum represents abnormally processed protein.

Fig. 211.2 Electron micrograph of iliac crest cartilage from a skeletally immature patient with diastrophic dysplasia. Large accumulations of abnormally thickened and aggregated type II collagen can be seen. The cross-banding was due to the thickened type II because no type I was identified on testing. Type II collagen is normally present in the cartilage matrix as thin, 10- to 15-nm-wide fibrils, but the molecular abnormalities in cartilage with diastrophic dysplasia allowed fibrils to aggregate.

the presence of missing or extra digits. Ultrasonography is especially of value in diagnosing lethal perinatal dysplasias in the second trimester because of the severity of the rib and long-bone abnormalities in this group. In the post-natal period, ultrasonography is helpful in evaluating the position and shape of the cartilaginous epiphyses before the formation of secondary ossification centers and in assessing the size of the cerebral ventricles in an infant.

Plain radiography

Plain radiography remains the most frequent and important method for evaluating a patient with a suspected skeletal dysplasia.¹¹ The skeletal survey, including radiographs of the skull, chest, spine, pelvis, and upper and lower extremities, can be diagnostic based on characteristic radiographic changes in specific bones. Such a survey will also assess the extent of deformity of the spine or appendicular skeleton and indicate the presence of osteoarthritis or inflammatory arthritis in specific joints. Radiographs of the cervical spine in flexion and extension are used to assess cervical stability, which may be compromised by odontoid hypoplasia.

Computed tomography

Computed tomography (CT) is most valuable for evaluating three-dimensional relationships in the skeleton. These relationships can be significantly altered, for example, in the hip, where acetabular dysplasia, subluxation, protrusio acetabuli, and coxa vara can occur, and in the cervical spine, where C1-C2 subluxation is common in disorders affecting odontoid development. CT may also be used as a quicker alternative to magnetic resonance imaging (MRI) when there is a question of enlarged cerebral ventricles.

Magnetic resonance imaging

MRI is of extreme importance in evaluating patients with skeletal dysplasias because of its ability to detect and differentiate soft tissue components such as muscle, fibrous connective tissue, cartilage, and blood vessels.¹² Joint structure, which is often abnormal in the dysplasias, can be assessed in terms of articular cartilage integrity, ligamentous continuity, capsular position, meniscal pathology, and even the vascularity of the epiphyseal cartilage through the use of gadolinium enhancement.

MRI may also be used to assess the impact of skeletal deformity on other organ systems, most commonly the central nervous system. In young children with achondroplasia, a small foramen magnum may impinge on the cervicomedullary junction and cause a high cervical myelopathy. Cine-MRI for evaluation of cerebrospinal fluid flow through the foramen magnum is a crucial tool in assessing the need for surgery in these children.

SPECIFIC REGIONAL SKELETAL ABNORMALITIES

Abnormalities of the spine (axial abnormalities)

Cervical spine

The possibility of spinal abnormalities should always be considered when evaluating a patient with skeletal dysplasia. Cervical abnormalities may easily lead to neurologic compromise. Anesthesiologists in particular must bear this in mind because of the extreme head and neck manipulation often needed for intubation. Abnormalities of the cervical spine were reported to occur in approximately 35 of the 150 defined dysplasia syndromes recognized in 1997.¹³ Symptoms generally develop slowly and often do not appear until adulthood even though the deformity has been present since birth. The clinical findings are typically those of a high cervical myelopathy.

Maldevelopment of the odontoid process with atlantoaxial instability¹⁴ predisposes to subluxation of the first cervical vertebra onto the second (C1-C2 subluxation) with spinal cord compression (Fig. 211.3). Treatment is generally posterior C1-C2 fusion or occiput-C2 fusion. This finding is frequently seen in Morquio disease (mucopolysaccharidosis type IV [MPS IV]) and is also very common in the type II collagenopathies (see Box 211.1).

Midcervical kyphosis is seen commonly with diastrophic dysplasia and occasionally with some of the type II collagenopathies. Some cases resolve with growth in the first few years of life, but those that do not may lead to progressive deformity. Other complications involving the cervical spine include cervical spina bifida occulta, cervical spinal cord stenosis (usually accompanied by foramen magnum stenosis in achondroplasia), and nerve root compression by exostoses in hereditary multiple exostoses.

Fig. 211.3 Lateral cervical radiograph from a patient with spondyloepiphyseal dysplasia congenita with quadriplegia showing C1 subluxation anteriorly (arrow) on C2.

Thoracolumbar spine

The thoracolumbar spine is affected in many of the skeletal dysplasias, with findings of scoliosis, kyphosis, or combined kyphoscoliosis. Flattening or irregularity of the vertebrae or intervertebral disks may be observed. Affected persons may require spinal fusion in childhood or adolescence. If untreated by surgery, the spinal deformity may increase in adulthood, unlike the idiopathic scoliosis observed in persons of average stature, which usually stabilizes once adult height is reached. Mid- to late-life osteoporosis may exacerbate this process.

Lumbar spine

Lumbar spinal stenosis may lead to nerve root compression compounded by intervertebral disk herniation in midadult life. In achondroplasia, caudal narrowing of the interpedicular distance often results in symptomatic spinal stenosis in adulthood (Fig. 211.4). Two other common skeletal dysplasias, diastrophic dysplasia and pseudoachondroplasia, are also typified by symptomatic spinal stenosis.

Abnormalities of the extremities (appendicular abnormalities)

Abnormalities of the extremities are practically universal in the skeletal dysplasias, even in conditions in which the trunk is more profoundly involved than the limbs. Shortening of the long bones is common, and most children with skeletal dysplasias come to medical attention because of short stature. In most dysplasias the shortening is symmetric, and one of four clinical patterns generally predominates.

Thus the shortening may be:

- Micromelic, in which all segments of the limb are short
- Rhizomelic, in which there is proportionally greater proximal shortening (humerus and femur)
- Mesomelic, in which shortening is concentrated in the midlimb regions (radius, ulna, tibia, fibula)
- Acromelic, in which the most marked shortening is distally in the hands and feet

Lower extremity length discrepancy with asymmetric shortening does occur, for example, in Ollier enchondromatosis and hereditary multiple exostosis. Other types of extremity deformity include angular bone deformity because of asymmetric physal involvement leading to varus, valgus, flexion, extension, or rotational malposition; limb deformity secondary to unequal growth rates of paired long bones in the forearm and leg; and joint

Fig. 211.4 Anteroposterior radiograph of the knee in a patient with pseudoachondroplasia illustrating the severe structural abnormalities that can occur in some dysplasias. Note the irregular surfaces of the distal end of the femur and proximal end of the tibia, varus angulation with lateral subluxation of the tibia and fibula, and irregular ossification of the medial tibial secondary ossification center and adjacent metaphysis (arrow). The lateral view showed a small, irregularly shaped patella, underdevelopment or overdevelopment of condylar cartilage shape, cruciate ligament and meniscal abnormalities, and capsular laxity. A tendency toward lateral patellar subluxation or full dislocation, often with underdevelopment of the lateral femoral condyle, may be observed.

contractures, instability, or articular or epiphyseal cartilage malformation, all of which can predispose to early osteoarthritis as a result of abnormal weight bearing.

Abnormalities of the hip

Many skeletal dysplasias are accompanied by hip abnormalities, which predispose to early osteoarthritis. Some pediatric orthopedic centers perform femoral and acetabular osteotomies during the growing years in an effort to forestall the degenerative changes. These surgeries often improve the structural relationship of the hip bones and gait. However, the skeletal pathology frequently affects the shape of the femoral head, including the articular surface and the structure of the cartilage matrix, so premature osteoarthritis is likely to develop. Structural defects of the hip in skeletal dysplasias with a known predisposition to osteoarthritis include congenital hip dislocation, acetabular dysplasia, coxa vara, hip contractures, and primary lack of sphericity of the femoral head. Multiple epiphyseal dysplasia, one of the most common of the skeletal dysplasias, frequently leads to hip and knee joint arthroplasty. Mutations in the type II collagen gene *COL2A1* have been found in several families with isolated osteoarthritis.¹⁵

Abnormalities of the knee

The knee is another joint commonly affected by the skeletal dysplasias, and early degenerative changes often develop (see Fig. 211.4). As in the hip, both structural abnormality leading to abnormal weight bearing and inherent cartilage abnormality in shape and molecular matrix composition predispose to arthritic changes. Genu varum or genu valgum deformity is common in many syndromes and frequently has associated rotational and flexion-extension components. These are due to epiphyseal abnormalities

in the distal end of the femur or proximal end of the tibia or both, including asymmetric growth plate involvement, underdevelopment or overdevelopment of condylar cartilage shape, cruciate ligament and meniscal abnormalities, and capsular laxity.

Ankle and foot abnormalities

Ankle and foot abnormalities are common in some dysplasias but in general are not as problematic as hip or knee involvement. Some disorders, such as hereditary multiple exostosis, have unequal growth of the distal ends of the tibia and fibula, with the shorter fibula leading to an ankle valgus that may require surgical correction. The equinovarus deformity of diastrophic dysplasia is notoriously difficult to correct surgically. In many syndromes the bones of the feet are affected by the dysplastic process and result in a foot that is shorter and wider than normal. This can make it difficult to find shoes that fit appropriately.

Upper extremity abnormalities

The upper extremities are the site of structural bone defects in many dysplasias, but the symptoms are often less frequent or severe than in the lower extremities because of the lack of weight bearing. As in the lower extremities, osteoarthritis is a common complication of conditions in which the underlying gene defect affects the structural integrity of articular cartilage. The type II collagenopathies are the most widely represented in this group. Patients may also have pain in the finger joints, elbow, and wrist because of asymmetric bone segment growth or ligamentous laxity. In hereditary multiple exostosis there can be dislocation of the radial head at the elbow and dorsal prominence and shortening of the distal part of the ulna with ulnar angulation of the hand (Madelung deformity). Wrist and hand involvement runs a wide gamut of possibilities, including shortened fingers (brachydactyly), shortened metacarpal bones, nail dysplasias, and loose or stiffened interphalangeal and metacarpophalangeal joints.

MANAGEMENT

Medical management

Despite recent advances in understanding the molecular pathogenesis of the skeletal dysplasias, management is still limited to symptomatic treatment and surgical correction of disabling deformities. It is important to know whether the disorder in question affects the articular cartilage surface either directly or indirectly. In many disorders, such as achondroplasia, which is the most common of the dysplasias, arthritis is rarely ever present because the epiphyseal ends of the bone are of normal shape and the articular cartilage has no molecular matrix abnormalities. In other conditions, such as diastrophic dysplasia, secondary osteoarthritis is almost invariable in all joints, and the combination of epiphyseal malformation, flattening and irregularity of the articular cartilage surface, fibrosis of the cartilage, and joint contractures renders many patients either nonambulatory or ambulatory with extreme difficulty by their late teenage years, even with intensive orthopedic management. The type II collagenopathies and multiple epiphyseal dysplasias are commonly associated with early-onset osteoarthritis. Preventive measures in persons at high risk for early joint disease include an emphasis on low-impact aerobic exercise, such as aquatic aerobics and elliptical trainers. Treatment of the painful joint or joints in patients with a skeletal dysplasia includes conservative measures such as decreased use, rest, crutches, splints, and antiinflammatory medications. Enzyme replacement is under active investigation for patients with mucopolysaccharidoses.

Surgical treatment

Surgical treatment of the extremities can be of great help even in the years before skeletal maturity. Such procedures include osteotomies to restore anatomic bone alignment, patellar realignment, and arthroscopy or open arthrotomy to remove degenerative debris from affected joints. On the other hand, it is not generally advisable to operate on joints that appear to be structurally abnormal but are asymptomatic in the hope of preventing or retarding osteoarthritic changes. Many patients with dysplasia tolerate apparently abnormal structure for decades because the surrounding musculature and soft tissues have developed in that position from the fetal period onward and are often stressed pathologically by radical surgical repositioning.

Total joint arthroplasty is a frequent intervention for patients with these disorders in the adult years. Orthopedists are generally reluctant to insert prosthetic joints in young and even middle-aged adults because the likelihood of replacement of a prosthesis increases the longer that it is in place.

These decisions are based on patient tolerance for ongoing pain, physical dysfunction, and reduced health-related quality of life, as well as current practice standards. The initial results are generally favorable because the bone tissue is normal and the patients are otherwise healthy.

The most commonly indicated spinal surgery in this population is laminectomy, which is performed for correction of lumbar stenosis in persons with achondroplasia. Those taking care of any patient with a skeletal dysplasia when general anesthesia is being given must bear in mind the high incidence of cervical C1-C2 abnormalities, which are often asymptomatic, even into adulthood. Extreme neck movements in an anesthetized patient may cause neurologic damage. Some centers perform lateral neck radiographs in patients with skeletal dysplasia before general anesthesia even if no symptoms have been elicited by the history.

Over the past 2 decades the practice of distraction osteotomies, or limb-lengthening procedures, has become more widely accepted as an approach to increasing height in persons of short stature. There has been considerable controversy about the advisability of adopting this procedure as a standard of care, and extensive experience has been achieved in only a few of the most common skeletal dysplasias, such as achondroplasia.¹⁶

OVERVIEW OF COMMON SKELETAL DYSPLASIAS

Achondroplasia

Achondroplasia, the most common of the skeletal dysplasias, is caused by a mutation in the gene expressing fibroblast growth factor receptor 3 (FGFR3).¹⁷ In more than 98% of cases the mutation causing achondroplasia is a glycine-to-arginine substitution at amino acid 380. The diagnosis is frequently made in the first few days of life by an astute pediatrician or radiologist. An anteroposterior radiograph of the spine and pelvis characteristically shows a progressively narrowed interpedicular distance from L1 to S1 (Fig. 211.5), a horizontal acetabulum, and a small sciatic notch. Genu varum requiring tibial osteotomies is common in childhood. A thoracolumbar gibbus deformity is not uncommon in infancy but usually resolves with weight bearing. Extreme lumbar lordosis is common. There is little evidence of osteoarthritis, even in adult life.

Fig. 211.5 Anteroposterior radiograph of the lumbar spine in a patient with achondroplasia showing progressive narrowing of the interpedicular distance from L1 above to S1 below. The distance should normally increase with each descending level.

Limb lengthening involving bilateral femoral and tibial distraction osteotomies may add up to 12 inches to adult height. Patients with achondroplasia are usually good candidates for this procedure because their cartilage is normal.

Other disorders caused by mutations in the *FGFR3* gene include the lethal thanatophoric dysplasia and the much milder hypochondroplasia.

Multiple epiphyseal dysplasia

This disorder has many subtypes in clinicoradiographic classifications, and not surprisingly, a number of different genes have been found to underlie it. Although the condition is a true skeletal dysplasia, not all patients are of short stature and many with severe joint involvement are normal to tall in terms of overall height. Those with multiple epiphyseal dysplasia represent the most common diagnostic group that undergoes total joint arthroplasty. The pattern of joint involvement varies in the different subtypes of multiple epiphyseal dysplasia. Involvement is often limited to the hips, and it tends to be bilateral. The radiographic appearance in those with hip involvement in the first decade superficially resembles the appearance in Legg-Calvé-Perthes disease, but there are several notable differences. In contrast to Legg-Calvé-Perthes disease, children with multiple epiphyseal dysplasia are usually minimally symptomatic or asymptomatic, range of motion is good, and the bilateral appearance is close to symmetric. In Legg-Calvé-Perthes disease, however, bilateral involvement develops in only about 20%, with second-side involvement occurring 18 to 24 months later than the first side. Molecular abnormalities in multiple epiphyseal dysplasia include mutations in genes encoding cartilage oligomeric protein (COMP) and collagen type IX.

Spondyloepiphyseal dysplasia

Radiographic features, including involvement of the epiphyses and flattening of the vertebrae, typify this class of dysplasia, which has a wide range of severity. Mutations in type II collagen are seen in the autosomal dominant forms of this condition. The more severe variants have extremely short stature with a short trunk and relatively long arms and legs. There is a high incidence of bilateral coxa vara and C1-C2 subluxation because of odontoid hypoplasia (see Fig. 211.3), along with increased risk for neurologic deficits. Cleft palate is observed in a minority of affected persons. Nonskeletal features include vitreoretinal degeneration with retinal detachment and progressive sensorineural hearing loss.

Kniest dysplasia

This disorder is also associated with mutations in type II collagen and tends to be on the more severe end of the spectrum of type II collagenopathies. Profound skeletal abnormalities are evident at birth. Craniofacial features include a depressed nasal bridge and cleft palate. In many patients, hearing problems develop in the second decade, and severe eye problems develop in others, including myopia, glaucoma, and retinal detachment, which may lead to blindness. The skeletal deformity is marked and progressive. Moderate to severe kyphoscoliosis is seen. The joints are characterized by dramatic widening of the epiphyses. Contractures can develop, and by the late second or early third decade, marked clinical and radiographic osteoarthritis may be present. The hips, knees, and ankles have considerable involvement. Procedures such as realignment osteotomy, patellar realignment, and knee joint débridement are helpful in alleviating the symptoms.

Diastrophic dysplasia

This disorder is one of the most deforming of the skeletal dysplasias, with severe short stature exacerbated by scoliosis, kyphosis, and fixed flexion contractures of the hips, knees, and feet and ankles (equinus and metatarsus adductus). The incidence of posterior cervical spina bifida is high; it is usually asymptomatic but must be recognized if cervical fusion is performed. Many patients become nonambulatory by the end of the second decade.

Correction of deformity often requires osteotomy, but even this can be followed by relentless recurrence. The disorder is further worsened by osteoarthritis with degeneration of articular cartilage because of misshapen epiphyses and inherent structural abnormality of the cartilage matrix, which is excessively fibrotic, thus limiting normal growth and function.

Diastrophic dysplasia is due to a mutation in the gene encoding the diastrophic dysplasia sulfate transporter (DTDST), which also causes two lethal dysplasias, atelosteogenesis type 2 and achondrogenesis type 1B. Growth plate cartilage is characterized histologically by increased deposition of fibrous tissue.

Morquio disease

Morquio disease (MPS IV) is the most common MPS syndrome compatible with longevity. The major enzyme deficiency involves galactose-6-sulfatase, which leads to imperfect processing of keratan sulfate. Patients are mentally normal and physically healthy but suffer from severe short stature, marked bilateral hip coxa vara, and acetabular dysplasia with a waddling gait, genu valgum, and a shortened spine with platyspondyly. Frequently, odontoid hypoplasia leads to C1-C2 instability with cervical myelopathy. Surgical stabilization of the C1-C2 junction is often required.¹⁸

Hereditary multiple exostoses

In this autosomal dominant disorder, multiple exostoses, or osteochondromas, are present at the periphery of the growth plates and metaphyses. They grow from cartilage caps via the endochondral sequence, and the bone of the exostosis is contiguous with metaphyseal bone with no interposition of cortical bone.

Three genes have been associated with multiple exostoses: *EXT1*, *EXT2*, and *EXT3*. *EXT1* and *EXT2* are proteins with glycosyltransferase activities needed for the synthesis of heparan sulfate, a proteoglycan present both on cell surfaces and in the extracellular matrix. Growth of the exostoses is normally controlled such that it ceases when the adjacent physeal growth stops. Recurrence of growth in adulthood in any of the osteochondromas is usually a sign of malignant transformation of persisting cartilage, generally a chondrosarcoma. The frequency of malignant transformation has been estimated to be approximately 5%.¹⁹

The osteochondromas themselves can cause discomfort, especially at or near skeletal maturation, when involution of the cartilage cap exposes bone tissue to surrounding tendon. Surgical excision is often indicated.

Asymmetric growth of paired long bones because of the presence of osteochondromas can contribute to the angular deformation leading to genu valgum, ankle tilt into valgus, dislocation of the radial head at the elbow, and wrist deformation with a dorsally displaced and shortened ulna (Madelung deformity). Complications occurring toward the end of growth and early in the adulthood may include pain and swelling behind the knee secondary to pseudoaneurysm of the popliteal artery caused by a pointed posteromedial exostosis, weakness of the foot and ankle secondary to stretching of the peroneal nerve by osteochondroma of the fibula, and radicular nerve symptoms secondary to an intraspinal osteochondroma growing against a nerve root.

CONCLUSION

This brief overview of the skeletal dysplasias has highlighted the increasing knowledge gained from genetic and molecular findings in the various syndromes. Awareness of the clinical complications associated with these disorders is important because most have a negative impact on the musculoskeletal system and many compromise neurologic function as well. Osteoarthritis, a common feature of many dysplasias, is frequently responsive for a considerable time to nonsurgical management, but many patients with progressive osteoarthritis eventually benefit from arthroplasty. The disorders represent a highly active field of investigation concerning the interplay between molecular and clinical pathology.

Bone tumors

■ EDWARD F. MCCARTHY

- Any adult older than 50 years with a new bone lesion should be considered to have metastatic carcinoma until ruled out, which requires biopsy.
- Multiple myeloma also occurs in older adults and should be considered after metastatic carcinoma is ruled out.
- Primary bone tumors generally occur in adolescents and young adults.
- More than 60 subtypes of primary bone tumors are recognized.
- Classification of primary bone tumors is based on what bone-related tissue they reproduce.
- Most primary bone tumors are benign.
- Many benign primary bone tumors have diagnostic radiographic features and need not undergo biopsy.
- Malignant bone tumors are low grade and high grade. Low-grade neoplasms require margin-free excisions. High-grade malignant bone neoplasms require chemotherapy in addition to excision.

INTRODUCTION

Bone tumors may be divided into three categories: metastatic tumors in bone, hematologic malignancies involving bone, and primary bone tumors. The first category, metastatic tumors in bone, are most common in middle-aged and older patients. Metastatic lesions in bone may have a wide variety of radiographic appearances. Because they are the most common cause of bone lesions in older patients, any patient older than 50 years with a radiographic bone lesion should be considered to have metastatic carcinoma until proved otherwise. Metastatic carcinomas generally indicate stage IV of the patient's disease. Because cure is not possible, it is the job of the treating physician to manage pain and preserve the structural stability of the skeleton.

The second category, hematologic malignancies in bone, also tend to favor older adults. These tumors include multiple myeloma and malignant lymphoma of bone. Multiple myeloma, though not as common as metastatic carcinoma in bone, should also be considered when any older patient has a bone lesion. Multiple myeloma has a wide range of radiographic features, and older patients with bone lesions should also have serum studies performed to rule out myeloma. Malignant lymphoma of bone is often a manifestation of a stage IV lymphoma that began, as lymphomas usually do, in the lymph nodes. However, malignant lymphomas may occasionally begin primarily in bone. In this setting the prognosis is often good.

Primary malignant bone tumors, the third category, are tumors that begin in bone and differentiate along tissue lines that are normally associated with bone, such as cartilage, fibrous tissue, and osteoid. Primary bone tumors are most common in adolescents and young adults. They can be both benign and malignant. More than 60 subtypes are recognized on the basis of tissue differentiation. Many primary bone tumors have diagnostic radiographic features. If benign, biopsy may not need to be performed, and some may be managed by observation. In contrast, biopsy is needed for primary malignant bone tumors to ensure proper treatment.

METASTATIC CARCINOMA IN BONE

Although carcinomas in any organ can spread to bone, the most common are carcinomas of the lung, breast, prostate, kidney, and thyroid. Primary

carcinoma of these organs is the most common of all cancers and accounts for half of the 1.3 million new cases of cancer each year in the United States.¹ Although the incidence of bone metastases in all patients dying of cancer is reported to be as high as 70%, it is probably higher. Therefore, because about 525,000 Americans die of cancer each year, diagnosis and management of bone metastases are an enormous clinical burden.

In men, the most common metastatic tumors are from the lung and prostate. Formerly, before widespread screening for prostate-specific antigen (PSA), almost a third of patients already had bone metastases when the diagnosis of prostate cancer was made.² With PSA screening, this incidence is falling. In patients with lung carcinoma, bone marrow involvement is present in 5% to 21% of patients at diagnosis. Small cell carcinoma is the most common type of tumor to metastasize.

In women, in contrast, breast carcinoma is the most common type of tumor to metastasize. As many as 21% of patients will have bone marrow metastases at the time of diagnosis,³ and probably all of the 45,000 women who die of breast cancer each year in the United States have bone metastases.

Carcinomas usually metastasize within 2 years, so a destructive bone lesion is easily connected to the primary cancer diagnosis. However, some cancers may not metastasize until years after primary therapy. For example, a metastasis from a breast carcinoma may develop 20 years after mastectomy. Usually, a patient has more than one bone lesion. Even though only one lesion may be symptomatic, a technetium bone scan will, in 90% of cases, demonstrate other sites of involvement. Occasionally, however, only a single metastatic focus is present.

Metastatic carcinoma in bone is remarkable for its wide range of plain radiographic patterns. In contrast to most primary bone tumors, which have distinctive, often diagnostic plain radiographic features, metastatic carcinoma can look like anything. Lesions may be radiolytic or radiodense; they may be permeative or well defined; or they may periosteal, intracortical, or intramedullary. The only distinctive feature of metastatic carcinoma in bone is its predilection for the axial skeleton, particularly the spine.

Certain metastatic carcinomas, however, produce consistent radiographic patterns. For example, metastatic prostate cancer usually produces radiodense lesions—so-called osteoblastic metastases. Sometimes, the osteoblastic metastases of prostatic carcinoma are widely distributed throughout the entire skeleton. Breast carcinoma can also be osteoblastic, but the lesions are often mixed osteolytic and osteoblastic (Fig. 212.1).

Metastatic lung carcinoma, by contrast, almost always produces radiolytic lesions (Fig. 212.2). Lesion can be permeative or well defined, and cortical destruction is often present.

Histologically, the characteristic feature of metastatic carcinoma in bone is an organoid growth pattern of neoplastic cells (Fig. e212.1). The cells are grouped in tight clusters or lines separated by a fibrous stroma. Frequently, the clusters assume a glandular shape, a pattern suggestive of adenocarcinoma. Pathologists have more than 100 immunohistochemical stains that can be used to determine the primary site of the carcinoma in most cases.

HEMATOLOGIC MALIGNANCIES

Multiple myeloma

Multiple myeloma is a malignant manifestation of plasma cell dyscrasia that results in bone lesions.⁴ Although plasma cells do not normally reside in bone marrow, multiple myeloma is regarded as a primary bone tumor. Other malignant plasma cell dyscrasias include solitary myeloma of bone, osteosclerotic myeloma, and amyloidosis of bone.

Fig. e212.1 Photomicrograph ($\times 40$) of metastatic carcinoma in bone. An organoid growth pattern is present where the cells cluster in small groups. This represents metastatic lung carcinoma.

Fig. 212.1 Radiograph of a pelvis showing poorly defined radiodense lesions (arrows). These lesions are osteoblastic metastases from metastatic breast carcinoma.

Fig. 212.2 Radiograph of the proximal end of a femur showing a poorly defined lytic lesion involving the greater trochanter (arrow). This is a focus of osteolytic metastatic lung cancer.

Multiple myeloma accounts for approximately 1% of all malignancies in the United States each year, with an annual incidence of about 13,000 cases.⁵ This disease is twice as common in blacks and more common in males than in females (1.6:1.0). It is second in incidence only to Hodgkin disease among the nonleukemic hematologic malignancies. Multiple myeloma is a

disease of older adults and is generally discovered between the ages of 50 and 80 years. Therefore it should be considered in the differential diagnosis of all lytic bone lesions in patients in this age range. Less than 2% of cases occur in patients younger than 40. The etiology of myeloma is not known, although genetic, racial, occupational, and environmental factors have been implicated in some studies.⁶ Myeloma often has the most insidious and nonspecific manifestation. Pain, present in two thirds of patients, is the most common symptom.⁴ Back and chest pain (secondary to rib fractures) occur commonly. Unlike the pain of metastatic bone disease, which is worse at rest and at night, the pain of multiple myeloma is precipitated by movement. The pain is often sudden in onset, and many patients remember the exact date and time that it began.

The most common radiographic changes of myeloma, however, are multiple discrete punched-out lytic bone lesions. They are most commonly seen in the skull, spine, pelvis, and proximal end of the femur or humerus. Lesions vary in size from 3 to 4 mm to 5 to 10 cm. They have well-defined borders and lack a sclerotic rim. In long bones a circular or elliptic lytic area may be seen on the endosteal bone surface.⁷ Larger lesions cause extensive cortical destruction (Fig. e212.2). Histologically, myeloma is composed of sheets of atypical plasma cells (Fig. e212.3).

Malignant lymphoma

Malignant lymphomas may secondarily involve bone marrow as a manifestation of disseminated disease. For example, bone marrow may be involved in disseminated small lymphocytic lymphomas and in many small cleaved cell lymphomas. In these low-grade lymphomas, bone involvement does not necessarily carry a poor prognosis, and plain radiographs often do not show osseous abnormalities. In addition, secondary bone involvement may occur in patients with stage IV, high-grade lymphomas. However, bone involvement in these patients indicates a poor prognosis.

In contrast to secondary osseous involvement, a malignant lymphoma may involve bone without evidence of nodal or visceral disease. Patients with this disease, known as *primary malignant lymphoma of bone*, have a more favorable prognosis than do those with secondary bone involvement. Primary malignant lymphoma of bone may occur at any age; patients range in age from 1.5 to 86 years, with a mean of 46 years.⁸ Any bone may be involved, and 29% of patients have multiple osseous sites of involvement. The mandible, maxilla, femur, pelvis, and spine are the most common locations. Patients have pain, often for longer than a year's duration. Some patients with a lymphoma at the epiphyseal end of a bone have a joint effusion secondary to neoplastic involvement of joint structures.

Malignant lymphomas are characteristically diffusely permeative lytic lesions that often involve a large segment of the affected bone. Lesions have varying amounts of intraosseous reactive bone, which imparts a mottled appearance (Fig. e212.4).

Malignant lymphomas of bone are usually diffuse, large cell, noncleaved lymphomas. The neoplastic cells are generally uniform with a large round nucleus and clumped chromatin; cytoplasm is scant (Fig. e212.5). However, some osseous lymphomas have cells with cleaved or even multilobed nuclei. Also, in rare cases the cells may be pleomorphic and have abundant cytoplasm, a pattern consistent with immunoblastic lymphoma. Osseous lymphomas in children may be of the lymphoblastic type and have small cells with round nuclei and fine chromatin.

Malignant lymphomas of bone are almost always B-cell neoplasms. Lymphoid origin is confirmed with a CD45 (leukocyte common antigen) stain, and B-cell lineage is confirmed with a CD20 stain. The latter stain differentiates neoplastic cells from the inflammatory infiltrate, which usually consists of many T lymphocytes.

Lymphomas of bone, without nodal or visceral disease, have a favorable prognosis. Generally, younger patients do better. Irradiation plus adjuvant chemotherapy yields a 5-year survival rate of 50% to 88%. Patients with multifocal osseous disease but without soft tissue involvement also do well, with 40% surviving for 5 years.

PRIMARY BONE TUMORS

Bone-forming neoplasms

Bone island

A bone island, also known as an *enostosis*, is a focus of dense compact bone within the medullary cavity. This nonneoplastic lesion most probably results from a remodeling error during skeletal growth. Although it is a developmental abnormality, a bone island may be mistaken radiographically for a neoplasm. Patients are asymptomatic. Therefore a bone island is almost

Fig. e212.2 Radiograph of an expansile lytic lesion of the proximal end of the radius. This is an example of a large focus of plasma cell myeloma.

Fig. e212.3 Photomicrograph (x40) showing sheaths of atypical malignant plasma cells.

Fig. e212.5 Photomicrograph (x60) of a large B-cell lymphoma from the patient in [Figure e212.4](#).

Fig. 212.3 Radiograph of a bone island in the proximal end of the humerus with sharp margins. This patient was asymptomatic. A well-defined radiodensity is apparent.

always discovered incidentally when a radiograph taken for other reasons. A bone island can occur in any bone, and occasionally, several bones may be involved.

A bone island can usually be diagnosed with certainty by plain radiography. A well-defined round or oval radiodensity is present in the medullary canal, usually in the metaphysis (Fig. 212.3). The degree of radiodensity is comparable to the cortex. The size varies, but most are 1 mm to 2 cm in diameter. The margins of a bone island are generally sharply circumscribed.

Histologically, a bone island is a well-defined island of lamellar compact bone identical to the cortex. Also, mature haversian canals are usually present.

Osteoid osteoma

Osteoid osteomas are benign osteoid-producing neoplasms with three important characteristics: small size, self-limited growth, and a tendency to cause extensive reactive changes in adjacent tissues. The lesional tissue of an osteoid osteoma, known as a *nidus*, is almost always only 1 cm or less in diameter. Despite its small size, the lesional tissue causes intense pain and provokes an exuberant periosteal reaction, a reaction that often obscures the small nidus.⁹

Like most other primary bone tumors, osteoid osteomas affect children and young adults. Most cases occur between the ages of 10 and 35, with the average being 19 years. Rarely, children younger than 5 years or adults older than 35 may be affected.¹⁰ Patients invariably complain of pain. Characteristically, the pain is worse at night and dramatically relieved by aspirin. This feature is present in more than 75% of cases and is an important diagnostic clue.

In addition to pain, the highly irritative nature of osteoid osteomas affects adjacent tissues. These local effects may be due to the prostaglandin synthesis demonstrated in some osteoid osteomas. For example, a lesion in the spine can cause scoliosis, and a lesion near a growth plate can stimulate lengthening of the extremity. Also, an intraarticular lesion may cause an intense synovitis. These intraarticular osteoid osteomas, particularly inside the hip or elbow capsule, may be difficult to diagnose because the bone inside a joint capsule lacks a periosteum and therefore lesions in these locations cannot stimulate the typical periosteal reaction. Another local effect of some osteoid osteomas is significant edema in adjacent soft tissues. A final effect of some osteoid osteomas is muscular atrophy and osteopenia in the involved extremity.

Osteoid osteomas may occur in any bone, but lesions in the femur and tibia account for 50% of cases. Other sites of predilection include the posterior elements of the spine (the vertebral body is a very rare location), the humerus, and the small bones of the hands and feet.

Osteoid osteomas have a very characteristic radiographic appearance. A small radiolucent nidus is surrounded by dense reactive bone. The nidus may be subperiosteal, intracortical, or subcortical (Fig. e212.6). On rare occasion the nidus is deep in the medullary canal. Occasionally, the reactive bone may be so dense that it obscures the nidus. In this situation, the small radiolucent focus in the center of the radiodense area can usually be identified with computed tomography (CT) or magnetic resonance imaging (MRI).

Histologically, osteoid osteomas are characterized by thin interconnecting seams of osteoid or woven bone lined by osteoblasts (Fig. e212.7). The osteoid seams are separated by loose fibrous stroma with prominent vascularity. This lesional tissue is sharply demarcated from the dense surrounding bone.

Osteoblastoma

Osteoblastomas are benign bone-forming neoplasms that share many histologic features with osteoid osteomas. However, these neoplasms differ in several important ways. First, osteoblastomas are rare neoplasms, unlike osteoid osteomas, which are relatively common. Second, osteoblastomas are larger than osteoid osteomas. Third, unlike the self-limited growth of osteoid osteomas, osteoblastomas grow progressively.

Osteoblastomas may occur at any age; however, 80% occur between the ages of 10 and 25. Patients usually have pain, and some have local swelling and tenderness. Any bone may be involved, including the calvaria and the small bones of the hands and feet. The spine, however, is the most common location and accounts for about a third of reported cases. In this location the vertebral posterior elements are the principal site of involvement, but occasionally the vertebral body may also be involved. Osteoblastomas almost never involve the vertebral body alone. All portions of the spine, including the sacrum, are equally affected. In the appendicular skeleton, the diaphysis or metaphysis of long bones, particularly the femur or tibia, is the most common location.

Radiographically, osteoblastomas are expansile, lytic lesions with variable amounts of fluffy mineralization (Fig. e212.8). Reported lesions have ranged from 1 to 11 cm. Most are well circumscribed, and occasionally they have a sclerotic rim. Many osteoblastomas expand the cortex and are bounded by a thin shell of reactive bone. Histologically, osteoblastoma is identical to osteoid osteoma, although the lesions are larger (Fig. e212.9).

Osteosarcoma

Osteosarcomas are malignant bone tumors whose cells have the ability to synthesize osteoid. Osteosarcoma is the most common primary malignant bone tumor. They have a wide range of histologic and radiographic patterns that can be subdivided into numerous osteosarcoma variants. Such variants include conventional osteosarcoma, parosteal and periosteal osteosarcoma, telangiectatic osteosarcoma, well-differentiated osteosarcoma, and others. These variants have characteristic radiographic and histologic features. The most common type of osteosarcoma is a high-grade interosseous osteosarcoma known as conventional osteosarcoma.

Conventional osteosarcoma accounts for 90% of all osteosarcomas.¹¹ It begins in the medullary canal and sometimes penetrates the cortex and invades the adjacent soft tissues. Most patients with conventional osteosarcoma are adolescents or young adults. About 85% of patients are younger than 30 years, with the peak incidence occurring at 20 to 25 years of age. This neoplasm is extremely rare in children younger than 10 years. Conventional osteosarcoma may also develop in older adults, although many have predisposing factors such as Paget disease or previous radiation therapy. In younger patients, conventional osteosarcoma most commonly occurs around the knee, with the distal end of the femur accounting for a third of all cases. By contrast, osteosarcoma develops in older patients more commonly in the flat bones. Pain, tenderness, and swelling, rarely present for more than a few months, are the usual initial symptoms.

The radiographic features of conventional osteosarcoma are diagnostic in two thirds of cases. The lesion has poorly circumscribed medullary lucency with mottled areas of radiodensity (Fig. 212.4). Occasionally, a lesion may be entirely radiodense. Cortical destruction is usually present, and there is often a focally mineralized soft tissue mass. Benign, periosteal reactive bone forms a Codman triangle adjacent to the soft tissue mass. In the long bones, conventional osteosarcoma is usually centered in the metaphysis.

Conventional osteosarcoma cells synthesize abundant osteoid. Seams or sheets of eosinophilic osteoid are distributed in a sarcomatous stroma

Fig. e212.6 Computed tomography scan of an osteoid osteoma in the talus. A well-defined lytic area contains a focal radiodensity characteristic of osteoid osteoma.

Fig. e212.7 Macrophotomicrograph of an osteoid osteoma in the medullary canal of bone.

Fig. e212.8 Axial computed tomography scan of a cervical vertebra showing an expansile radiolytic lesion in the pedicle of the vertebrae. This pattern is characteristic of osteoblastoma.

Fig. e212.9 Medium-power photomicrograph (x60) of an osteoblastoma showing seams of mineralized osteoid in a loose fibrovascular stroma.

Fig. 212.4 Radiograph of an osteosarcoma of the distal femoral metaphysis. A poorly defined radiolytic lesion with associated radiodensity is present. Extraosseous spread of radiodensity and a Codman triangle proximally (arrow) can be seen.

(Fig. e212.10). The stromal cells of conventional osteosarcoma are usually high grade. They show varying degrees of atypia and numerous mitotic figures. The pattern and distribution of osteoid are often variable. In some areas, osteoid is deposited in fine lacelike seams.

Parosteal osteosarcoma is the most common osteosarcoma variant after conventional osteosarcoma. This neoplasm is a low-grade fibroblastic osteosarcoma that is limited to the surface of bone. Radiographically, an irregular bony protrusion projects from the bone surface like a multilobulated door knob (Fig. 212.5). Only in rare circumstances is the medullary canal of the bone involved. The posterior aspect of the distal end of the femur is the most common location. Histologically, parosteal osteosarcoma shows interlacing seams of osteoid in a low-grade fibroblastic stroma (Fig. e212.11). This neoplasm has low potential to metastasize and does not require chemotherapy. Lesions can be cured by *en bloc* resection with tumor-free margins.

Cartilage neoplasms

Chondroblastoma

Chondroblastoma is a rare benign neoplasm of fetal-type cartilage differentiation. Though reported in patients ranging in age from 3 to 72 years, more than 50% of lesions develop in patients between the ages of 15 and 25. Approximately 70% of chondroblastomas occur in the long bones, most commonly the proximal end of the humerus, followed by the distal end of the femur and proximal end of the tibia.¹² In the long bones, the center of the lesion is almost always the epiphysis. Other bones commonly involved are the proximal end of the femur, the small bones of the feet, and the temporal bone of the skull. Patients generally complain of pain. In addition, because of epiphyseal involvement, joint symptoms, such as stiffness or effusion, are common.

Radiologically, chondroblastoma is usually a well-circumscribed lytic lesion that when in a long bone, involves the epiphysis (Fig. 212.6). About 50% of lesions extend into the metaphysis, a feature usually seen only when the epiphyseal plate is closed. Most lesions lack a sclerotic rim. Varying degrees of stippled calcification are present in 40% of lesions, the remainder being completely lucent. Chondroblastomas average 4.3 cm in maximum dimension, but they may be as large as 19 cm. Occasionally, they expand or destroy the cortex.

Fig. 212.5 Radiograph of a parosteal osteosarcoma of the posterior aspect of the distal end of the femur. An irregular bony mass projects from the bone surface.

Fig. 212.6 Radiograph of a chondroblastoma of the proximal femoral epiphysis. The lesion is a well-defined lytic area with a circumferential zone of reactive bone.

Histologically, chondroblastoma is composed of sheets of stromal cells, scattered multinucleated giant cells, and varying amounts of chondroid matrix (Fig. e212.12). The stromal cells, resembling fetal chondroblasts, are distinctive. They are round with abundant cytoplasm and generally have distinct cytoplasmic membranes. The nuclei are also round and are located in the center of the cytoplasm, thus giving the cells a “fried egg” appearance. The nuclei have faintly clumped chromatin and often have a grooved or folded membrane.

Chondromyxoid fibroma

Chondromyxoid fibroma, when in a long bone, is a metaphyseal lesion that usually abuts against one cortex. Occasionally, lesions involve a portion of the epiphysis if the plate is closed. In all locations, chondroblastomas are radiographically well-circumscribed lytic lesions and often have a sclerotic

Fig. e212.10 Medium-power photomicrograph (x60) of an osteoblastic osteosarcoma showing sheets of malignant osteoid amid atypical rounded sarcoma cells.

Fig. e212.11 Low-power photomicrograph (x20) of a parosteal osteosarcoma showing interlacing strands of osteoid in a bland fibrous tissue background.

Fig. e212.12 Medium-power photomicrograph (x60) of chondroblastoma showing rounded stromal cells and numerous multinucleated giant cells.

Fig. 212.7 Radiograph of a chondromyxoid fibroma of the proximal femoral metaphysis. This well-defined lytic lesion has a sclerotic margin.

margin (Fig. 212.7). Some lesions, particularly in the pelvis, have a multiloculated, “soap bubble” appearance, and some have a scalloped margin. Lesions range in size from 2 to 10 cm in maximum dimension.

Chondromyxoid fibroma has distinctive histologic features. Elongated or stellate cells are present in an abundant extracellular chondroid matrix (Fig. e212.13). Two important low-power features are a lobular growth pattern and sharp demarcation from surrounding bone. Cellularity is variable, but each lobule tends to be more cellular at the periphery. The peripheral cells are more spindle shaped and appear to separate the lobules by fibrous bands. The fibrous bands contain blood vessels and, frequently, osteoclast-like giant cells.

Enchondroma

An enchondroma is a hamartomatous proliferation of mature hyaline cartilage in the medullary canal of the metaphysis or metadiaphysis. The origin of this lesion is thought to be due to a portion of the epiphyseal plate becoming entrapped in the metaphysis during bone growth. These lesions are common. Approximately 2% of all people have a small cartilaginous island in the medullary canal of the femur, presumably caused by this entrapment mechanism. These rests are undoubtedly present in other bones as well. The cartilaginous islands, subject to the same growth factors as epiphyseal plate cartilage, cease to grow in adulthood.

Enchondromas most commonly involve the tubular bones of the hands and feet. In fact, enchondromas are the most common bone tumor of the hand. The long bones are also frequent sites, particularly the tibia, distal end of the femur, and proximal end of the humerus. Rarely, the pelvis is involved.

Enchondromas in adulthood are generally asymptomatic; they are discovered incidentally on radiographs or bone scans obtained for other reasons. Large enchondromas or enchondromas in the hand may, however, produce pain from a stress fracture. Enchondromas may be discovered at any age, but most are found in persons between the ages of 15 and 40.

Enchondromas show the characteristic mineralization pattern of hyaline cartilage—radiodense rings and stipples (Fig. 212.8). Occasionally, the mineralization is very dense. Characteristically, the clusters of ringlike and stippled mineralization are well defined and can be traced in a continuous line. In adults, enchondromas vary in size from 1 cm to almost 10 cm in maximum dimension. Histologically, islands of hyaline cartilage are present (Fig. e212.14).

Osteochondroma

Osteochondromas are hamartomatous proliferations of bone and cartilage that arise from the cortex and project into soft tissue (Fig. 212.9). They are

Fig. 212.8 Radiograph of an enchondroma of the proximal end of the tibia showing stippled and ring-shaped calcifications. This patient was asymptomatic, and the lesion was found incidentally.

Fig. 212.9 Radiograph of an osteochondroma of the proximal end of the tibia arising from the metaphysis. A “ring and stippled” radiodensity in the head of the lesion is present, consistent with cartilage.

thought to develop from islands of epiphyseal plate cartilage entrapped beneath the periosteum during skeletal growth. The cartilage rests grow and ossify at the same rate as adjacent bone. When skeletal maturity is reached, osteochondromas stop growing. Osteochondromas are probably the most common tumorous process of bone. The true incidence cannot be calculated because many are asymptomatic. Some are discovered incidentally on radiographs taken for other reasons. Most osteochondromas are solitary. Symptomatic lesions usually occur before 30 years of age. Large osteochondromas are manifested clinically as firm subcutaneous masses. Pain may be caused by fracture of the stalk, nerve impingement, or inflammation of an overlying bursa. Osteochondromas may arise from any bone formed in cartilage, but the distal end of the femur, proximal end of the tibia, proximal end of the humerus, and pelvis are the most common sites.

Histologically, an osteochondroma consists of a cartilage cap overlying a stalk of cortical and trabecular bone (Fig. e212.15). The cartilage cap is bounded by a well-defined perichondrium that separates the lesion from the surrounding soft tissue. Often, particularly in large osteochondromas, islands of partially calcified and ossified cartilage are present inside the stalk, indicative of cartilage entrapment during growth.

Fig. e212.13 Photomicrograph (×20) of a chondromyxoid fibroma showing a lobulated proliferation of myxoid cells in a faint chondroid background.

Fig. 212.10 Radiograph of a periosteal chondroma of the proximal end of the humerus. A well-defined zone of lucency is seen in the proximal end of the humerus along with margin buttresses suggestive of a surface lesion.

Periosteal chondroma

Periosteal chondroma, also known as juxtacortical chondroma, is a benign proliferation of hyaline cartilage on the bone surface beneath the periosteum. Lesions range in size from 1 to 5 cm in diameter and may involve any bone in the appendicular skeleton, although the proximal or distal ends of the femur and the proximal end of the humerus are the most common sites. Patients are generally between the ages of 10 and 30 years, and they have usually have pain, often for longer than a year.

Radiologically, periosteal chondromas, unlike osteochondromas, lack a bony stalk. In a periosteal chondroma, a well-demarcated aggregate of ring-like and stippled densities is directly adjacent to the cortex (Fig. 212.10). The cortex is intact under the cartilaginous mass, although it is usually scalloped or cratered. Buttresses of reactive bone are occasionally present at the margins of the lesion.

Histologically, periosteal chondromas show lobules of hyaline cartilage on the external surface of the cortex beneath the periosteum (Fig. e212.16). Frequently, networks of reactive and endochondral bone separate the hyaline cartilage lobules. The cartilage is mildly cellular, and sometimes the nuclei are plump and hyperchromatic. Occasionally, the cartilage matrix shows myxoid changes.

Periosteal chondromas are best treated by *en bloc* excision of the cartilage, including the overlying perichondrium and the underlying cortex. Recurrence after complete removal is rare.

Chondrosarcoma

Chondrosarcomas are malignant neoplasms of cartilage-producing cells. After osteosarcoma, chondrosarcoma is the second most common primary malignant bone tumor. Unlike most other primary bone tumors, chondrosarcomas tend to occur in older patients and have a predilection for the axial skeleton.

Chondrosarcomas may be divided into two major categories: *central chondrosarcomas* (Fig. e212.17) and *surface chondrosarcomas* (Fig. 212.11). They occur with equal frequency. Central chondrosarcomas are centered in the medullary canal and occasionally penetrate through the cortex. By contrast, surface chondrosarcomas, also known as peripheral chondrosarcomas, arise on the bone surface and grow into the adjacent soft tissue.

Chondrosarcomas show a wide range of aggressiveness. Some lesions, though locally aggressive, grow slowly and rarely metastasize. By contrast, other chondrosarcomas are very destructive and metastasize readily. Fortunately, most chondrosarcomas (about 75%) grow slowly. In general, the aggressiveness of a chondrosarcoma can be predicted by its cellularity and degree of nuclear atypia, features known as “histologic grade.” High-grade lesions permeate through the marrow cavity (Fig. e212.18).

The higher the grade of the chondrosarcoma, the poorer the prognosis. Grade 1 chondrosarcomas have a low incidence of metastasis and can often

Fig. 212.11 Radiograph of a surface chondrosarcoma of the pubic symphysis showing a mass of rings and stippled calcifications consistent with a chondrosarcoma.

be cured by local incision. Wide radical incision is required for higher-grade chondrosarcomas. Generally, chondrosarcomas do not respond to chemotherapy or radiotherapy.

Fibrous neoplasms

Nonossifying fibroma

Nonossifying fibromas are common developmental proliferations of fibrous tissue that occur in the metaphyseal region of long bones. Although the cause of these lesions is unknown, they are probably due to exaggerated subperiosteal osteoclastic resorption during metaphyseal remodeling. This exaggerated resorptive process often begins at the site of tendon insertions.¹³ Small lesions, known as fibrous cortical defects, result from the same process. Though forming in the metaphysis, lesions migrate into the diaphysis as the bone grows.

Nonossifying fibromas most commonly involve the distal end of the femur and the distal or proximal end of the tibia, sites that account for 80% of lesions. The flat bones, the small bones of the hands and feet, the spine, and the craniofacial skeleton are not affected. Many nonossifying fibromas are asymptomatic and discovered incidentally on radiographs obtained for other reasons. Undoubtedly, many are never diagnosed. Large nonossifying fibromas may cause pain, and some are diagnosed after a pathologic fracture. Symptoms, when present, usually develop when patients are in their mid-teens. Development of a nonossifying fibroma before 5 years of age is extremely rare.

Radiographically, nonossifying fibromas are lytic metaphyseal lesions. Characteristically, the lesions are eccentric in the medullary canal and are juxtaposed to one cortex (Fig. 212.12). In addition, the margins are scalloped and a sclerotic rim is usually present. Small lesions, from 1 to 2 cm, are regarded as fibrous cortical defects. Alternatively, some lesions reach 7 cm in maximum diameter and cause cortical expansion.

Histologically, nonossifying fibromas consist of a spindle cell stroma with scattered small multinucleated giant cells, although the giant cells may be scarce. Characteristically, the spindle cells are arranged in a whorled or storiform pattern. Occasionally, the stroma is very cellular and the spindle cells often have plump hyperchromatic nuclei.

Small asymptomatic nonossifying fibromas need no therapy. Most heal spontaneously over a period of several years. Larger lesions, particularly those that expand the cortex or are accompanied by pathologic fractures, should be treated by curettage and bone grafting. Recurrence after treatment is very rare.

Fibrous dysplasia

Fibrous dysplasia is a common skeletal lesion characterized by a hamartomatous proliferation of fibroosseous tissue in the medullary canal. This tissue proliferates during skeletal growth and, in some cases, continues to grow during adulthood. The bone involvement in fibrous dysplasia exhibits a wide spectrum of severity. In about 80% of cases only a small focus of one bone is affected, a condition known as monostotic fibrous dysplasia. Multiple bones are involved in the remainder of patients, the so-called

Fig. e212.16 Lower-power photomicrograph of a periosteal chondroma (x2) showing a well-defined island of cartilage sitting on the bone surface. The medullary canal is not involved.

Fig. e212.17 Radiograph of a high-grade central chondrosarcoma. There are rings and stipules characteristic of cartilage associated with a poorly defined lucency and destruction of the lateral cortex of the tibial metaphysis.

Fig. e212.18 Photomicrograph (x40) of a chondrosarcoma showing basophilic cartilage infiltrating throughout the marrow spaces.

Fig. 212.12 Radiograph of a nonossifying fibroma of the distal tibial metaphysis. A well-defined lytic area is surrounded by a sclerotic rim. The lesion is centered on the cortex.

polyostotic fibrous dysplasia. In this form, fibrous dysplasia may involve long segments of bone, and it may cause significant cortical expansion. Occasionally, polyostotic fibrous dysplasia involves only one extremity.

Fibrous dysplasia may occur in any bone. In the axial skeleton, the craniofacial bones and ribs are the most common sites. The tibia and proximal end of the femur are the preferred sites in the appendicular skeleton. Fibrous dysplasia is often asymptomatic—lesions are discovered on plain radiographs taken for other reasons. Although lesions develop during skeletal growth, 25% of cases are not diagnosed until after 30 years of age.

Some patients with severe polyostotic fibrous dysplasia also have pigmented skin lesions and endocrine abnormalities. Patients with this condition, known as McCune-Albright syndrome, have severely deformed bones and are usually symptomatic before 10 years of age. In McCune-Albright syndrome the skin lesions are often confined to one extremity. Some patients with this syndrome also have soft tissue myxomas. McCune-Albright syndrome is now known to be a genetic mutation caused by a mosaic state of an activating mutation in the *GNAS1* gene. This gene codes for an adenosine diphosphate-dependent G protein.¹⁴

The radiologic features of fibrous dysplasia are often diagnostic. In the appendicular skeleton, fibrous dysplasia is typically an elongated lesion with symmetric cortical thinning and expansion—the characteristic “long lesion in a long bone” (Fig. 212.13). Although most lesions have a “ground-glass” texture, some may be entirely radiolytic; others may be radiodense. In severely involved weight-bearing bones, deformity is common because of multiple fractures. Histologically, fibrous dysplasia shows irregular seams of woven new bone in a cellular fibrous stroma. The seams of bone are thin and disconnected and are arranged in curved shapes reminiscent of “Chinese letters” or “alphabet soup” (Fig. e212.19).

Malignant fibrous histiocytoma

Malignant fibrous histiocytomas are high-grade sarcomas with fibrohistiocytic differentiation. Some pathologists refer to this neoplasm as high-grade undifferentiated pleomorphic sarcoma. In addition to occurrence in bone as a primary lesion, this neoplasm is the most common sarcoma to complicate preexisting osseous lesions such as radiation damage, Paget disease, and cartilaginous neoplasms. Moreover, malignant fibrous histiocytomas may, on rare occasion, occur as a complication of a bone infarct.¹⁵ In this situation the sarcoma probably develops in the reparative granulation tissue at the margin of the infarct.

Fig. 212.13 Radiograph of a typical lesion of fibrous dysplasia in the fibula (arrow) showing a long lesion in a long bone with a characteristic “ground-glass” appearance.

Primary malignant fibrous histiocytomas may involve any bone.¹⁶ However, the femur is the most common site (one third of cases), followed by the tibia and humerus. Patients range in age from 6 to 81 years, but more than 50% of cases occur in individuals older than 40 years. Patients have pain, and 67% have swelling or a mass. Some patients are initially found to have a pathologic fracture.

Radiographically, malignant fibrous histiocytomas are poorly defined radiolytic lesions, often with extensive cortical destruction, and periosteal new bone reaction is unusual (Fig. e212.20). MRI often shows an associated soft tissue mass. Malignant fibrous histiocytoma most commonly involves the metaphyseal region of bone. However, secondary involvement of the epiphysis is common.

Malignant fibrous histiocytomas are composed of spindle cells, histiocytic cells, or an intermingled combination of the two in varying proportions (Fig. e212.21). The spindle cells are arranged in a storiform pattern, the most characteristic feature of malignant fibrous histiocytoma. The nuclei are oval and vesicular with mild to moderate pleomorphism.

Giant cell tumor

Giant cell tumor of bone, sometimes referred to as conventional giant cell tumor, is a benign locally aggressive neoplasm that usually affects young adults; about two thirds of patients are between the ages of 20 and 40. Giant cell tumors may occasionally occur in the elderly—a patient 74 years old has been documented.¹⁷ However, these neoplasms are extremely rare in growing children. Less than 2% of giant cell tumors affect patients younger than 15 years.

Giant cell tumors occur most commonly in the distal end of the femur, proximal end of the tibia, and distal end of the radius. These locations account for about 65% of cases. Other common locations include the pelvis, vertebral bodies, and proximal end of the femur. Patients almost always have pain and a few have a pathologic fracture.

Giant cell tumors, when they occur in long bones, have a diagnostic radiographic pattern. A well-defined lytic lesion involves both the epiphysis and the metaphysis and almost always extends to subchondral bone (Fig. 212.14). The epiphyseal plate is almost always closed. At least one cortex is thin and may also be expanded or destroyed. In the flat bones, giant cell tumors are also well-defined lytic lesions without a sclerotic rim.

Histologically, giant cell tumors consist of multinucleated giant cells admixed with mononuclear stromal cells (Fig. e212.22). The stromal cells are polygonal or slightly elongated. Mitotic figures are numerous in the

Fig. e212.19 Lower-power photomicrograph (x2) of fibrous dysplasia showing a fibrous lesion with many curved deposits of osteoid assuming a "Chinese letter" pattern.

stromal cells. The multinucleated giant cells, often numerous, resemble osteoclasts.

Ewing sarcoma

Ewing sarcoma and its differentiated subtype peripheral neuroectodermal tumor (PNET) of bone are the most malignant of all the primary bone tumors. They are the most common tumors in the group called “small round blue cell tumors.” Other neoplasms in this group are primary lymphoma of bone, small cell osteosarcoma, and mesenchymal chondrosarcoma. A genetic abnormality that distinguishes Ewing sarcoma from other neoplasms is the characteristic chromosomal translocation $t(11;22)(q24;q12)$.¹⁸ Other small round blue cell tumors, such as embryonal rhabdomyosarcoma and neuroblastoma, are not primary osseous tumors but may involve bone secondarily.

Ewing sarcoma is not uncommon. It accounts for as many as 15% of all primary malignant bone tumors and is the fourth most common bone malignancy after myeloma, osteosarcoma, and chondrosarcoma.¹⁹ Ewing sarcoma occurs in patients younger than those with all other primary malignant bone tumors. Although patients range in age from 5 months to 47 years, 8% are between the ages of 5 and 20 years.²⁰ Any bone may be affected, but involvement of the femur and pelvis account for a third of cases. A characteristic feature of both Ewing sarcoma and PNET is a very large soft tissue mass adjacent to the involved bone. Patients have pain, and many have signs and symptoms that mimic acute osteomyelitis: fever, leukocytosis, and an elevated sedimentation rate. Occasionally, patients have a pathologic fracture.

The very aggressive growth of Ewing sarcoma and PNET is evident radiographically. Both neoplasms show a highly permeative growth pattern with a periosteal new bone reaction (Fig. e212.23). The periosteal reaction may be of the “onion skin” or the “sunburst” pattern. The diaphysis of bone is the usual location; however, the metaphysis is also sometimes affected. The intraosseous component of some lesions may be so highly permeative that plain radiographs may be interpreted as normal. In such cases, a minimal periosteal reaction may be the only clue to the presence of a neoplasm. MRI or a bone scan, however, reveals long segments of marrow involvement. In addition, MRI often shows an adjacent soft tissue mass.

Histologically, Ewing sarcoma and PNET consist of broad fields of small uniform round cells with scant cytoplasm (Fig. e212.24). The nuclei are round and contain fine chromatin. Nucleoli are usually inconspicuous.

Osteofibrous dysplasia/adamantinoma

Osteofibrous dysplasia and adamantinoma are two lesions at either end of a spectrum of neoplasms that involve only the tibia. Osteofibrous dysplasia is a benign fibroosseous process, and adamantinoma is a low-grade malignant neoplasm. It is possible that an adamantinoma is a malignant version of osteofibrous dysplasia. However, it is extremely rare for a lesion of osteofibrous dysplasia to transform into an adamantinoma.

Osteofibrous dysplasia is a fibroosseous proliferation that affects the bones of children, almost always before they are 10 years old. The distinctive feature of this lesion is its predilection for one site—the anterior cortex of the tibia (Fig. e212.25).

Histologically, osteofibrous dysplasia is characterized by irregular new bone trabeculae amid cellular fibrous tissue, a pattern reminiscent of fibrous dysplasia. However, unlike the trabeculae of fibrous dysplasia, which seem to appear *de novo* in the fibrous stroma, the trabeculae of osteofibrous dysplasia are lined by plump osteoblasts.

Osteofibrous dysplasia is a nonneoplastic, self-limited process. Lesions grow slowly until skeletal maturity, and thereafter they stabilize. Small lesions are sometimes asymptomatic and disappear spontaneously. Large lesions, even those that have resulted in architectural deformity, stop growing. Therefore surgical removal of these lesions should be avoided. Curettage during the proliferative phase is almost always followed by recurrence. Surgery should be reserved for lesions causing severe deformity or pseudarthrosis.

Adamantinoma, at the malignant end of the spectrum, is a very rare neoplasm. Patients range in age from 3 to 72 years, but most are in their 20s and 30s. Almost all lesions occur in the midshaft of the tibia, and in 10% of cases the ipsilateral fibula is involved. On rare occasion, other long bones, such as the femur, humerus, and ulna, may be involved. This neoplasm has also been reported in the pretibial soft tissues.²¹ Patients usually complain of pain and swelling, often of long duration. Approximately a third of patients have had symptoms for longer than 5 years. One patient was reported to have symptoms for 50 years.²²

Adamantinomas share some radiologic features with osteofibrous dysplasia. For example, adamantinomas are also cortical-based lesions, and 90% of cases involve the diaphysis. In addition, like osteofibrous dysplasia, adamantinomas show multiloculated lytic areas surrounded by dense reactive bone. Frequently, the lesions appear multifocal and involve long segments of the tibial shaft. However, two radiographic features help distinguish adamantinomas from osteofibrous dysplasia. The first, seen in 10% of cases, is cortical penetration and involvement of soft tissues. Second, most cases of adamantinoma have one or more foci of medullary canal involvement, a feature not usually seen in osteofibrous dysplasia (Fig. e212.26).

Histologically, adamantinomas consist of various patterns of epithelial cells in a fibrous and fibroosseous stroma.

Adamantinomas are low-grade malignant neoplasms. They should be treated by wide segmental resection or amputation. Metastases develop in about 25% of patients after surgical ablation. Metastasis may occur as late as 16 years after surgery.²³

Vascular neoplasms

The nomenclature of vasoformative bone lesions has been confusing. Terms such as “epithelioid hemangioma” and “hemangioendothelial sarcoma” create artificial categories that can possibly lead to improper therapy. Vascular lesions of bone are best subdivided into three major categories: hemangioma, epithelioid hemangioendothelioma, and angiosarcoma.

Hemangiomas in the skeleton may be solitary or multiple. Solitary hemangiomas usually affect a vertebral body or the calvaria (Fig. e212.27). Small lesions can be found at autopsy in 11% of carefully examined spines.²⁴ Most spinal hemangiomas are asymptomatic and discovered incidentally on radiographs obtained for other reasons. Some patients, however, have back pain because of a compression fracture. Hemangiomas of the calvaria are usually manifested as a slowly growing mass. They may be discovered at any age, but most patients are in their 40s.²⁵

Radiographically, vertebral hemangiomas are lytic lesions with coarse vertical striations, the so-called jail bar pattern. These dense striations on cross-sectional CT scans appear as spots of dense bone. Lesions in the calvaria bulge the outer cortical table and have a “sunburst” appearance of reactive bone.

Epithelioid hemangioendotheliomas are indolent neoplasms characterized by the proliferation of plump, histiocytoid endothelial cells.²⁶ Most epithelioid hemangioendotheliomas of bone are diagnosed in patients between the ages of 10 and 30, although this lesion may also develop in older individuals. The femur, pelvis, and tibia are the most common sites.

Fig. e212.26 Radiograph of an adamantinoma in the posterior aspect of the tibia showing a poorly defined lytic lesion with involvement of the medullary canal.

Fig. e212.27 Macrophotograph of a specimen of two vertebrae showing a hemangioma in the medullary canal with infiltration of the trabecular spaces (arrow).

Patients usually have pain or a pathologic fracture. A distinctive feature of epithelioid hemangioendothelioma, present in 64% of patients, is involvement of multiple sites. Curiously, multicentric lesions tend to involve the bones of one extremity. Although any bone may be involved, the bones of the lower extremity are favored sites.

Epithelioid hemangioendothelioma of bone is usually a well-circumscribed radiolytic defect ranging in size from 2.5 to 15 cm in maximum dimension. A mildly sclerotic border is occasionally present. Sometimes this neoplasm is multifocal in the adjacent bones (Fig. e212.28). On rare occasion the lesions may be predominantly sclerotic. Cortical expansion and extension into the soft tissue may occur occasionally.

Epithelioid hemangioendotheliomas of bone are characterized by nests, cords, or sheets of plump, round, or polygonal cells with abundant eosinophilic cytoplasm. Their nuclei are round and moderately hyperchromatic. These “histiocytoid” cells, which show little pleomorphism, often contain intracytoplasmic lumina that may coalesce with similar structures in an adjacent cell (Fig. e212.29). Frequently, the cell nests form well-developed vascular lumina that contain red cells. In some areas the clusters of histiocytoid endothelial cells are separated by a fibrovascular stroma containing lymphocytes, plasma cells, and often many eosinophils.

Epithelioid hemangioendotheliomas of bone are slow-growing neoplasms with a protracted clinical course. Lesions should be removed totally, either by complete curettage or by limb-sparing resection. Radiotherapy may be of value if complete excision is impossible. Lesions with more than mild mitotic activity may be more aggressive. Patients with epithelioid hemangioendothelioma should be evaluated for multifocal lesions. These patients have an equally good and perhaps better prognosis.

Angiosarcomas of bone are very rare, highly malignant neoplasms that develop in patients from the ages of 10 to 70. Most, however, are older than 30 years. Pain of several weeks' to a few months' duration is the usual symptom prompting evaluation. Angiosarcomas most commonly involve the femur and tibia.

Angiosarcomas of bone have the radiographic pattern of an aggressive, high-grade malignant bone tumor. Lesions are radiolytic with poorly defined margins, and cortical expansion and cortical destruction are usually present (Fig. e212.30).

Histologically, these lesions have anastomosing blood-filled clefts and slits. These spaces are lined by large cells with abundant eosinophilic cytoplasm. Unlike the uniform cells of epithelioid hemangioendotheliomas, the cells of angiosarcomas show marked pleomorphism. Large, bizarre, hyperchromatic nuclei are common, and mitotic figures are numerous. Papillary tufts of the pleomorphic cells often project into the neoplastic vascular lumina (Fig. e212.31).

Chordoma

Chordomas, thought to arise from notochordal rests, are slow-growing malignant neoplasms that occur exclusively along the spinal axis.²⁷ The two ends of the spinal axis, inside the skull and the sacrococcygeal region, are the most common locations. Half of all chordomas arise in the sacrococcygeal region, where they are associated with pain and occasionally bladder dysfunction. At the other end of the spine, intracranial chordomas, which account for 40% of lesions, involve bones at the base of the skull. When chordomas occur in this region, patients have headache and neurologic impairment. The remaining 10% of chordomas involve the vertebral column. These locations correlate with the distribution of notochordal rests found

Fig. 212.15 Magnetic resonance image of a chordoma consisting of a large well-defined mass anterior to the sacrum.

by meticulous study of adult and developing spines.²⁸ Most patients with a chordoma are older than 40, although intracranial lesions occur in some—what younger patients.

Radiologically, sacral chordomas are intraosseous destructive lesions that often expand into soft tissues. Sometimes these neoplasms consist of midline paraspinal or intrapelvic masses with minimal or no bone destruction (Fig. 212.15). Chordomas are best studied with CT. Intracranial chordomas may destroy the sella turcica, and they frequently invade the petrous or sphenoid bone. Occasionally, intracranial chordomas calcify, a feature rarely present in chordomas of the sacrum and spine.

The histologic features of chordomas are distinctive. On low power, a lobular growth pattern, similar to cartilage neoplasms, is apparent. Cords and sheets of cells are embedded in an abundant, pale extracellular matrix. Higher-power study reveals two types of cells. One is a square to oblong cell with a round central nucleus and an eosinophilic cytoplasm. The other type contains a round nucleus but has bubbly cytoplasm (physaliferous cell) (Fig. e212.32). Chordomas show little nuclear pleomorphism, and mitotic figures are rare. They are epithelial neoplasms and are strongly positive for cytokeratin. Stains for epithelial membrane antigen and S-100 protein are also positive. However, the stain for S-100 protein is usually only weakly positive.

Chordomas are aggressive neoplasms that can rarely be excised completely. Removal often requires sacrifice of the cauda equina. Palliative debulking followed by radiation therapy is the most common therapy. Typically, patients suffer multiple recurrences. Metastasis, usually to the lungs, skin, or bones, occurs in 3% of sacral or vertebral chordomas.²⁹ More than 90% of patients die within 10 years.

 in systemic sclerosis
 classification based on, 1154-1155, 1154t
 implicated in tissue damage, 1185, 1186t
 nuclear, 1185-1187
 as serologic feature, 1174
- Autoantigens
 as possible targets of immune response in rheumatoid arthritis, 758-759
 in systemic lupus erythematosus, 1075-1079, 1078t, 1079f
 cell membrane, 1079
 characteristics of, 1081
 DNA, nucleosomes, and chromatin, 1077-1078
 PCNA, RNA helicase A, Ku, and Su, 1078-1079
 phospholipid-dependent, 1079
 ribosomal P0, P1, and P2, 1078
 Ro60 (SS-A) and La (SS-B), 1076-1077
 Sm and RNP, 1076
- Autoimmune disease and menstrual cycle, 188
- Autoimmune responses with TNF inhibitors, 506
- Autoimmunity, 119, 125-126
 to cartilage components in animal models of arthritis, 743, 744f
 in complex regional pain syndrome, 687
 dysbiosis as trigger for, 146f, 147
 in Sjögren syndrome, 1136
 Toll-like receptors and, 131-132, 132f
- Autoinflammation and PLC λ 2-associated antibody deficiency and immune dysregulation (APLAID), 1387
- Autoinflammatory diseases, monogenic. *See* Monogenic autoinflammatory diseases.
- Autologous chondrocyte/cartilage implantation (ACI), 160-161
 for osteochondritis dissecans, 639, 639f
- Autologous stem cell transplantation
 for juvenile idiopathic arthritis, 859
 peripheral, for systemic sclerosis, 1192t, 1193
- Automated data collection approaches in systems biology, 135
- Autonomic nervous system in inflammation, 179-180
- Autophagosomes in antigen presentation, 122, 123f
- Autophagy in antigen presentation, 122, 123f
- Avascular necrosis. *See* Osteonecrosis.
- Average cost-effectiveness ratio, 20
- Avocado/soybean unsaponifiables (ASU), 387
 for osteoarthritis, 1512
- Axial arthritis associated with inflammatory bowel disease, 281-282, 281f
- Axial involvement, 227, 227t
- Axial joints, multidetector CT of, 315, 318f-319f
- Axial skeletal dysplasias, 1730
 cervical, 1730, 1730f
 lumbar, 1730, 1731f
 thoracolumbar, 1730
- Axial spondyloarthritis (axSpA)
 bursitis in, 968, 968f
 classification of, 941-942, 943f, 943t, 949
 clinical features of, 946-950
 chest wall involvement as, 946
 costochondritis as, 967-968, 967f
 enthesitis as, 946, 968, 968f
 fatigue and psychosocial manifestations as, 948
 hip and shoulder involvement as, 946
 inflammatory back pain as, 946, 947t
 peripheral arthritis as, 946
 defined, 960
 diagnosis of, 232t, 941-942
 differential diagnosis of
 of sacroiliac joints, 963
 of spine, 965-967
 vs. blood vessels, 965-967, 966f
 vs. degenerative changes, 965, 965f-966f
 vs. diffuse idiopathic skeletal hyperostosis, 965, 966f
 disability and socioeconomic impact of, 949
 extraarticular manifestations of, 947-948
 atlantoaxial subluxation as, 948
 cardiac, 947-948
 gastrointestinal, 947
 neurologic, 948

- Axial spondyloarthritis (axSpA)
(*Continued*)
osteoporosis as, 948
pulmonary, 948
renal, 948
spinal fractures as, 948, 965-967, 967f
spondylodiskitis as, 948, 965
uveitis as, 947, 947t
genetics of, 956-959
in Africans, 958-959
in East Asians, 957-958
epidemiology of, 956, 957t
MHC genes in, 119-121, 120f, 956, 957f
non-MHC genes in, 956-957, 958t
imaging of, 960-969
of extravertebral manifestations, 967-968, 967f-968f
future perspectives on, 968, 968.e1f
overview of, 960, 961t
of sacroiliac joints, 961-963
conventional radiography for, 961f-962f, 962
CT for, 962, 962f
differential diagnosis in, 963
MRI for, 962-963, 962f-963f, 963t
scintigraphy for, 962
technical aspects of, 960-961, 961f
of spine, 963-967
with cauda equina syndrome, 967, 967f
conventional radiography for, 963-964, 964f
differential diagnosis in, 965-967, 965f-967f
MRI for, 964-965, 964f-965f, 964t
technical aspects of, 960-961, 961f
for MRI, 960-961
immunopathology of, 953
investigations of, 949
life span with, 949
management of, 970-985
anti-TNF- α blocking agents for, 977-982
adalimumab as, 979-980
adverse events with, 981
biologic basis of, 977-978
certolizumab as, 980
etanercept as, 978-979
golimumab as, 980
infliximab as, 978, 978f-980f
juvenile, 981
for nonradiographic disease, 980
patient selection for, 981, 981f-982f
for peripheral arthritis and enthesitis, 981
prediction of good response to, 981-982, 982f
prevention of radiographic damage by, 980-981
with psoriasis and inflammatory bowel disease, 981
switching from one to another, 982
ASAS/EULAR recommendations on, 970, 971b, 972f
assessment of efficacy of, 970-972
ASAS criteria for, 970, 972t
BASMI (spinal mobility) for, 971, 973t
Bath criteria for, 970-971, 973f
imaging for, 971-972
laboratory tests for, 971
pooled indices for, 970-971
biologic agents for, 977
conventional DMARDs for, 976-977
methotrexate as, 976
other, 976-977
sulfasalazine as, 976
- Axial spondyloarthritis (axSpA)
(*Continued*)
corticosteroids for, 976
intraarticular, 976, 977f
systemic, 976
current perspectives on, 970, 971b, 972f
for extraarticular manifestations, 982-983
anterior uveitis as, 982-983
osteoporosis as, 983
historical perspective on, 970
NSAIDs for, 973-976, 975f, 975t
as disease modifiers, 975-976, 976f
physical therapy for, 972, 974f
surgical, 983-984
hip replacement as, 983-984, 983f
spinal, 983f-984f, 984
measures of disease activity and severity in, 949, 949b
natural history of, 949
pathognomic findings of, 960
physical examination findings in, 947
of pubic symphysis, 967-968
in women, 948-949
Axonal neuropathies in Sjögren syndrome, 300
axSpA. *See* Axial spondyloarthritis (axSpA).
Azathioprine (AZA, Imuran)
in breast milk, 460
efficacy of, 461, 461t
for lupus nephritis, 1115
mechanism of action of, 459, 460t
for myositis, 1251
in perioperative period, 563t
pharmacogenetics of, 408
pharmacokinetics of, 459-460, 460t
during pregnancy, 538t, 539
for systemic lupus erythematosus, 1103
in pregnancy and lactation, 1128, 1128t
for Takayasu arteritis, 1326
therapeutic use of, 461
toxicity of, 461, 462t
Azulfidine. *See* Sulfasalazine (SSZ, Azulfidine).
Azurophilic granules in inflammation, 170-172, 172t
- B**
- B cell(s)
activation and functions of, 122
autoreactive, in systemic sclerosis, 1186
bone marrow as niche for differentiation of, 167, 167f
development of, 121, 121f
and humoral immunity, 119, 121-122
in juvenile idiopathic arthritis, 847
in rheumatoid synovium, 771
role in autoimmune diseases of, 472-477
in Sjögren syndrome, 1139-1140
in systemic lupus erythematosus, 1083-1084
transitional, 121
B cell-activating factor (BAFF) in Sjögren syndrome, 1139-1140
B lymphocytes. *See* B cell(s).
Back pain
injury model vs. biopsychosocial model of, 72
low. *See* Low back pain.
due to osteoporotic fracture, 1644
Background therapy, 397-398
Backwash ileitis, 279
Bacteria as possible target of immune response in rheumatoid arthritis, 760
- Bacterial arthritis, 885-893
gonococcal, 891-893
clinical features of, 891-892, 892f
epidemiology of, 891
investigations of, 892, 892f
management of, 892-893
microbiology of, 891, 891f
pathogenesis of, 891
osteomyelitis as, 885-891
clinical features of, 887-888
differential diagnosis of, 889
epidemiology of, 885
imaging of, 889, 890f
investigations of, 888-889
long-bone, 887, 887f
management of, 891
microbiology of, 886, 886t
pathogenesis of, 886-887, 886f
vertebral, 887
prognosis for, 885
of prosthetic joint, 887-888, 888f
septic arthritis as, 885-891
clinical features of, 887
differential diagnosis of, 889
epidemiology of, 885
imaging of, 889, 890f
investigations of, 888-889
laboratory features of, 889, 889t
management of, 889-891, 890t
microbiologic testing for, 889
microbiology of, 885-886, 886t
pathogenesis of, 886, 886b, 886f
septic bursitis as, 888, 889f
syphilitic, 893
clinical features of, 893
investigations of, 893
management of, 893
Bacterial enteritis, 282, 282t
Bacteriophage λ as cloning vector, 87-88
BAFF (B-cell activation factor of the tumor necrosis factor family), 121
BAFF (B cell-activating factor) in Sjögren syndrome, 1139-1140
BAFF (B-cell activation factor of the tumor necrosis factor family) receptor, 104t, 105
Baker cyst, 642-643
corticosteroid injection for, 549, 550f
in osteoarthritis of knee, 1451-1452
rupture of, 708, 708f
BAL (bronchoalveolar lavage), 275
for systemic sclerosis, 1202-1204
Balance, rehabilitation for, 378
Balanced FFE imaging, 325
Balanced steady-state free precession (bSSFP) imaging, 325, 326f
Ball catcher's view, 307, 309f
Ballotement test, 635
Bamboo spine in inflammatory bowel disease, 281-282, 281f
Band cell, 171f
Bannwarth syndrome, 905
Bar graph, 201-202
Bare metal stents (BMSs), perioperative management of, 558
Baricitinib, 515, 516t
BASDAI (Bath Ankylosing Spondylitis Disease Activity Index), 970-971, 973f
Baseline observation carried forward (BOCF), 201
Basic calcium phosphate (BCP) crystal(s)
identification and characterization of, 1600, 1600f
intraarticular
clinical features of, 1597-1598, 1598f
acute synovitis as, 1597
additional, 1598, 1599f
chronic monoarthritis (with or without erosions) as, 1597
- Basic calcium phosphate (BCP) crystal(s)
(*Continued*)
large-joint destructive arthropathies as, 1598, 1598f
osteoarthritis as, 1598
imaging of, 1599
management of, 1603
nature of, 1601, 1601f
Basic calcium phosphate (BCP) crystal deposition, 1596-1603
articular calcification due to, 1596
calcific periarthritis due to
clinical features of, 1596-1597, 1597f, 1597t
differential diagnosis of, 1600
epidemiology of, 1596, 1597f
history of, 1596
imaging of, 1597f, 1598-1599, 1599f
management of, 1602
pathogenesis of, 1601
clinical features of, 1596-1598, 1597t
differential diagnosis of, 1600
epidemiology of, 1596, 1597f
etiology of, 1601
history of, 1596
intraarticular
clinical features of, 1597-1598, 1598f
acute synovitis as, 1597
additional, 1598, 1599f
chronic monoarthritis (with or without erosions) as, 1597
large-joint destructive arthropathies as, 1598, 1598f
osteoarthritis as, 1598
history of, 1596
imaging of, 1599
management of, 1603
investigations of, 1598-1600
biochemical, 1599-1600
identification of basic calcium phosphate crystals in, 1600, 1600f
imaging in, 1598-1599, 1599f
of synovial or bursal fluid, 1600
management of, 1602-1603
Milwaukee shoulder in
clinical features of, 1598, 1598f
epidemiology of, 1596
history of, 1596
imaging of, 1599, 1599f
management of, 1603
pathogenesis of, 1602
nature of crystals in, 1601, 1601f
in osteoarthritis
clinical features of, 1598
history of, 1596
identification and characterization of, 1600, 1600f
management of, 1603
pathogenesis of, 1601-1602
pathogenesis of, 1601-1602, 1602f
in scleroderma, 1598, 1599f
tumoral calcinosis due to
clinical features of, 1598
management of, 1602
pathogenesis of, 1601
Basic fibroblast growth factor (bFGF) in matrix repair, 158
Basic Local Alignment Search Tool (BLAST), 86
Basilar invagination

names and definitions of, 1274t
- Medullary cystic kidney disease (MCKD), 1561, 1572
- Mefenamic acid, 416t
- MEFV gene in familial Mediterranean fever, 1369, 1372
- Melanoma differentiation-associated gene 5 (MDA5) in innate immunity, 128
- Melatonin, lupus due to, 1090
- Meloxicam, 416t
for ankylosing spondylitis, 975t
for juvenile idiopathic arthritis, 855t
- Meltzer syndrome, kidney involvement in, 292t, 293, 293f
- Membrane cofactor protein (MCP), 176t
- Membrane-bound glucocorticoid receptors (mGCRs), 425f
- Membrane-permeable ligands that bind intracellular receptors, 113
- Membrane-type matrix metalloproteinases (MT-MMPs), 152-153, 153f
in murine models of disease, 157
- Membranoproliferative glomerulonephritis (MPGN), 291
- Membranous glomerulonephritis, 291
in systemic lupus erythematosus, 1036-1037, 1037f, 1057, 1058f
- Meningitis in rheumatoid arthritis, 717, 718f, 717.e1f
- Meningomyelocele, neuropathic arthropathy due to, 1521
- Meniscal damage in osteoarthritis, pain due to, 1448
- Meniscal injuries, 643-644, 644f
- Meniscectomy, 643-644, 644f
for induced osteoarthritis models, 1459
- Meniscus(i)
anatomy of, 633, 634f
discoid, 636, 637f
- Menstrual cycle and autoimmune disease, 188
- Mental component score (MCS) for rheumatoid arthritis, 797-798
- MEPE (matrix extracellular phosphoglycoprotein) in mineralization, 46, 46f
- Meperidine, dosing and conversion chart for, 412t
- Meralgia paresthetica, 678-679, 679f
- 6-Mercaptopurine during pregnancy, 538t, 539
- Meridians, 383, 383f
- Mesangial lesions in lupus nephritis, 1036-1037, 1036f, 1055-1056, 1055f
- Mesangial proliferative glomerulonephritis, 291
persistent, 294
- Mesangiocapillary glomerulonephritis, 291
- Mesenchymal stem cells (MSCs), 161-163
intraarticular injection of, 162f
matrix-guided application of, 162-163, 162f
trophic and immune suppressive effects of, 161
- Mesomelic skeletal dysplasia, 1730
- Metabolic acidosis due to renal osteodystrophy, 1696
- Metabolic diseases
calcium pyrophosphate crystal-associated arthropathy and epidemiology of, 1584
screening for, 1589
and gout, 1553
Toll-like receptors and, 132
- Metabolic effects
of glucocorticoids, 430
of hydroxychloroquine, 438
- Metabolic genes in gout, 1566
- Metabolic myopathies, 1230, 1255-1259
due to acid maltase deficiency (glycogenosis type II, Pompe disease), 1258, 1258t
due to carnitine palmitoyltransferase II deficiency, 1259
clinical features of, 1255
due to debrancher deficiency (Cori-Forbes disease, glycogenosis type III), 1257-1258
diagnostic approach to, 1255, 1256b
due to fatty acid oxidation disorders, 1258-1259
general principles of, 1255-1256
glycogen/glucose metabolism and defects in, 1256-1258, 1258t
mechanisms of, 1255, 1256f-1257f
ischemic forearm exercise test for, 1255-1257, 1258t
lipid metabolism and, 1255, 1257f
due to long-chain acyl-CoA dehydrogenase deficiency, 1259
mitochondrial, 1230, 1259
due to myoadenylate deaminase deficiency, 1259
due to myophosphorylase deficiency (McArdle disease, glycogenosis type V), 1256-1257
due to phosphofructokinase deficiency (glycogen storage disease type VII, Tarui disease), 1257, 1258t
serum creatine kinase in, 1255, 1256b

- Metabolic myopathies (*Continued*)
 due to trifunctional protein deficiency, 1259
 due to very-long-chain acyl-CoA dehydrogenase deficiency, 1259
- Metabolic syndrome and gout, 1573
- Metabolomics, 136t
- Metacarpal, 620f
- Metacarpophalangeal (MCP) flexion crease, 621f
- Metacarpophalangeal (MCP) joints, 620f
 corticosteroid injection of, 545, 545.e1f
 rheumatoid arthritis of, 705, 705f-706f
 imaging of, 728, 728f-729f
 ulnar deviation at, 216f
- Metagenomics, 136t
- Metalloproteinase-deficient mice, in models of disease, 157-158
- Metaphysis, 42
 in bone growth, 52f
 in bone modeling, 52, 52f
- Metastases, lumbar skeletal, 581f, 587, 587f
- Metastatic carcinoma in bone, 1734, 1735f, 1734.e1f
- Metastatic disease, musculoskeletal manifestations of, 1421, 1421f
- Metatarsal, 647.e1f
- Metatarsophalangeal (MTP) joints, 647.e3
 corticosteroid injection of, 550, 550f, 550.e1f
 gout of, 654, 654f
 osteoarthritis of, 1452, 1452f
- Methadone, 412
 dosing and conversion chart for, 412t
- Methotrexate (MTX, Rheumatrex), 443-450
 adverse effects of, 446-447
 common, 446-447, 447t
 hepatic toxicity as, 446-447
 other, 447
 with pneumococcal vaccination, 447
 pulmonary toxicity as, 447
 teratogenicity as, 447
 for ankylosing spondylitis, 976
 with infliximab, 978
 in combination with abatacept, 468-469
 drug interactions of NSAIDs with, 418t
 for early arthritis, 788
 and folic acid, 443-444, 445f
 folic acid supplementation with, 447
 for giant cell arteritis, 448t, 1307
 for juvenile idiopathic arthritis, 449, 852t, 856-857, 856t-857t
 lung injury due to, 277
 mechanism of action of, 443-444, 445f
 for myositis, 1250-1251
 in perioperative period, 563t
 pharmacogenetics of, 407-408, 407f, 408t
 pharmacogenomics of, 447-448
 pharmacology of, 443, 444f-445f
 for polymyalgia rheumatica, 1302
 during pregnancy, 538t, 539
 for psoriatic arthritis, 448-449, 1010
 recommendations on use of, 448, 448b
 for rheumatic diseases other than rheumatoid arthritis, 448-449, 448t
 for rheumatoid arthritis
 efficacy of, 444-446
 vs. biologic DMARDs, 444, 446t
 biomarkers of response in, 446
 in combination with biologic DMARDs, 446
 in combination with leflunomide, 453-454, 455f
 in combination with nonbiologic DMARDs, 446
 effect on mortality in, 446
 effect on structural damage in, 446
- Methotrexate (MTX, Rheumatrex) (*Continued*)
 in initial use, 444
 vs. leflunomide, 452, 452f-453f
 long-term studies of, 446
 vs. nonbiologic DMARDs, 444
 with synovitis, 804
 with rituximab, 475
 structure of, 443, 444f
 and sulfasalazine, 443
 for systemic lupus erythematosus, 448t, 1103
 in pregnancy and lactation, 1128t
 for systemic sclerosis, 1192, 1192t
 for Takayasu arteritis, 1326
 vs. tofacitinib, 512-513, 515t
- Methotrexate (MTX) polyglutamates, 443
- Methylation
 of DNA, 140
 histone, 140
- Methyl-CpG-binding protein 2 (MECP2), 131
- ^{99m}Tc-methylene diphosphonate (MDP) in bone scintigraphy, 342
- Methylenetetrahydrofolate reductase (MTHFR) gene, 407-408, 407f, 408t, 447-448
- Methylprednisolone, 424f, 424t
 for early arthritis, 788
 for lupus nephritis, 1114
 for myositis, 1248-1249
- Mevalonate kinase (MK) deficiency, 1370t, 1376-1378
 background of, 1376-1377
 clinical features of, 1377, 1377f
 complications of untreated, 1378
 genetics and pathophysiology of, 1372f
 laboratory findings in, 1377-1378
 treatment of, 1378
- MFSI (Multidimensional Fatigue Symptom Inventory) for osteoarthritis, 1493-1494
- mGCRs (membrane-bound glucocorticoid receptors), 425f
- MGHL (middle glenohumeral ligament), 595, 596f
- MHAQ (Modified Health Assessment Questionnaire) for rheumatoid arthritis, 798
- MHC. *See* Major histocompatibility complex (MHC).
- MIA (mono-iodoacetate) injection for induced osteoarthritis models, 1458
- MICA (MHC class I chain-related gene A) in psoriatic arthritis, 998
- Mice. *See* Mouse.
- Microalbuminuria, 287
- Microarteriolysis, radical, for Raynaud phenomenon, 1195t
- Microbiome, 145-151
 defined, 145
 and dysbiosis as trigger for autoimmunity, 146f, 147
 in inflammatory arthritis
 animal models of, 147-148, 148f
 human, 148-150
 in inflammatory bowel disease-related arthropathy, 149
 mucosal barriers and host-immune interactions in, 145-147
 physiologic intestinal inflammation and homeostasis in health and, 145-147, 146f
 in psoriasis and psoriatic arthritis, 149
 research methods for study of human, 147
 rheumatoid arthritis and, 149-150
 in spondyloarthritis, 148
- Microchimerism and systemic sclerosis, 1156
- β₂-Microglobulin amyloidosis, 295, 1409
 in chronic kidney disease, 1429-1430, 1429f
- Micro-magnetic resonance imaging for glucocorticoid-induced osteoporosis, 1676
- Micromelic skeletal dysplasia, 1730
- Microorganism-associated molecular patterns (MAMPs), 127
 Toll-like receptors and, 127
- MicroRNA, epigenetics and, 141f, 143
- Microscopic colitis, 283-284, 283t
- Microscopic polyangiitis (MPA), 1310-1321. *See also* Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis.
 ANCA testing for, 1315, 1315b, 1315f
 clinical features of, 292-293, 292t, 1310-1314
 cardiac involvement as, 1313
 gastrointestinal involvement as, 1313
 pattern of onset as, 1310-1311, 1311f
 pulmonary involvement as, 1312
 renal involvement as, 1313
 upper respiratory tract involvement as, 1311
 defined, 1274t
 differential diagnosis of, 1315-1317, 1316t
 disease assessment for, 1320
 epidemiology of, 1275-1276, 1276f, 1310, 1275.e1
 etiology and pathogenesis of, 1317, 1318f
 history of, 1310
 immunopathogenesis of, 1286-1287
 mortality and morbidity with, 1320
 pathologic features of, 1314-1315, 1314f
 treatment of
 for generalized and severe disease, 1318-1319
 for localized and early generalized disease, 1319
- Microscopic polyarteritis, kidney involvement in, 292-293, 292t
- Microsporidia spp, 903
- Microvascular dysfunction
 in complex regional pain syndrome, 687
 in systemic sclerosis, 1165-1166, 1167f
- Microvasculature in inflammatory myopathies, 1243
- Middle glenohumeral ligament (MGHL), 595, 596f
- Middle phalanx, 620f-621f
- Midfoot, 647.e1-647.e647
- Midfoot pain, 651
- Miglustat for Gaucher disease, 1709
- Migration studies, 5
- Migratory pattern of joint involvement, 228
- Mikulicz syndrome, 1131. *See also* Sjögren syndrome (SjS).
- Milgram classification, 643t
- Milnacipran for fibromyalgia, 667
- Milwaukee shoulder
 clinical features of, 1598, 1598f
 epidemiology of, 1596
 history of, 1596
 imaging of, 1599, 1599f
 management of, 1603
 in osteoarthritis, 1450, 1450f
 pathogenesis of, 1602
 synovial fluid analysis of, 238
- Mimecan, 38.e1
- Mincle (macrophage-inducible C-type lectin) in innate immunity, 129
- MINDFUL program (Mastering the Intellectual Navigation of Daily Functioning and Undoing the Limitations of Lupus), 1110
- Mineralization
 proteins involved in, 45-46
 dentin matrix protein-1 as, 46, 46f
 fibroblast growth factor 23 as, 45-46, 46f
 matrix extracellular
 phosphoglycoprotein as, 46, 46f
 PHEX as, 46, 46f
 secondary, 44
- Minimal anticipated biological effect level (MABEL), 207
- Minimal change disease, 291
- Minimal clinically important difference (MCID)
 for osteoarthritis, 1496
 for rheumatoid arthritis
 on HAQ, 798
 on SF-36, 797-798
- Minimally important difference, 198
- Minimally invasive procedures, 242-249
 arthrocentesis as, 242
 arthroscopic joint lavage as, 246-248
 biopsies as, 242-246
 abdominal fat pad fine-needle aspiration, 243-244, 244f
 arthroscopic, 246, 248f
 muscle/fascia, 244-245, 245f
 salivary gland, 245-246, 246f
 skin and subcutaneous tissue, 242-243, 243f-244f
 synovial, 246, 247f
 ultrasound-guided, 248
 of temporal artery, 244, 245f
- Minimum clinically important improvement (MCII)
 for osteoarthritis, 15
 for rheumatoid arthritis, 14-15
- Minocycline
 chemical structure of, 438
 dosing and monitoring of, 440
 for rheumatoid arthritis
 efficacy data on, 439, 439t
 long-term data on, 439
 meta-analysis of, 439
 toxicity data on, 439-440, 440f
 for systemic sclerosis, 1192t, 1194
- Minocycline-induced lupus, 1088
- MIRR(s) (multichain immune recognition receptors) in signal transduction, 114-115, 115f
- Mirror artifact, 334
- Miscarriage due to antiphospholipid syndrome
 management of, 1149
 pathogenesis of, 1144, 1145b
- Missing data, 201
 for images as outcome measures in clinical trials, 359-360

 noninvasive, 1537-1538
 management of, 1540
 overview of, 1536
 pathogenesis of, 1537f, 1539-1540
 radiographic findings in, 1536-1537, 1538f-1539f
- Ocrelizumab, 473
- Ocular involvement, 260-266
 in ANCA-associated vasculitis, 1311, 1312f, 1311.e1f
 in Behçet syndrome, 1330
 retinal vasculitis as, 263
 uveitis as, 261, 1330, 1330f
 in Cogan syndrome
 assessment of, 1297
 clinical features of, 1295-1296, 1296f
 management of, 1297-1298, 1297t
 corneal disease as, 264-265, 264f-265f
 keratoconjunctivitis sicca as, 265, 265f
 in Marfan syndrome, 1721
 in NOMID, 1380f, 1381
 optic nerve disease as, 264
- Ocular involvement (*Continued*)
 orbital disease as, 264
 in osteogenesis imperfecta, 1716
 perioperative management of, 564
 in relapsing polychondritis, 1402-1403
 retinal vascular disease as, 262-264, 263f-264f
 in rheumatoid arthritis, 716-717
 Brown syndrome as, 717
 corneal filamentary keratitis as, 716, 717f
 episcleral nodulosis as, 716
 episcleritis as, 716, 716f
 keratoconjunctivitis sicca as, 716
 scleritis as, 716
 scleromalacia as, 716, 716f
 ulcerative keratitis ("corneal melt") as, 716, 717f, 716.e1f
 uveitis as, 716
 in sarcoidosis, 1393
 scleral disease as, 262, 262f
 management of, 262
 in Sjögren syndrome, 1131, 1133b
 ophthalmologic examination for, 1137, 1138f
 structural elements in, 261f
 in systemic lupus erythematosus, 1042-1043
 in TNF receptor-associated periodic syndrome, 1375, 1376f
 uveitis as, 260-262, 261f
 management of, 261-262
- Ocular muscle, 261f
- Odds ratio, 6
- Odontoid peg, 707, 707f
- Ofatumumab, 473
- Ogilvie syndrome, postoperative, 561
- OH[•] (hydroxyl radical) in inflammation, 178, 178f
- OHOA-MRI (Oslo Hand Osteoarthritis MRI) score, 1488
- OI. *See* Osteogenesis imperfecta (OI).
- Olecranon bursa, 612
 corticosteroid injection of, 548, 548.e1f
- Olecranon bursal swelling in rheumatoid arthritis, 707
- Olecranon bursitis, 613-615
 clinical aspects of, 614-615
 differential diagnosis of, 614t
 etiology of, 613, 614f
 inflammatory, 614-615, 614t
 management of, 615
 traumatic, 614, 614t
- Olecranon fossa, 611
- Oligoarthritis
 psoriatic, 989-990
 selected causes of, 226, 226t
- OMERACT (Outcome Measures in Rheumatology Clinical Trials), 9
- Onchocerca volvulus*, 903
